Psychopharmacology has developed as a medical discipline over approximately the past five decades. The discoveries of the earlier effective antidepressants, antipsychotics, and mood stabilizers were invariably based on serendipitous observations. The repeated demonstration of efficacy of these agents then served as an impetus for considerable research into the neurobiological bases of their therapeutic effects and of emotion and cognition themselves, as well as the biological basis of the major psychiatric disorders. Moreover, the emergence of an entire new multidisciplinary field, neuropsychopharmacology, which has led to newer specific agents to alter maladaptive central nervous system processes or activity, was another by-product of these early endeavors. The remarkable proliferation of information in this area—coupled with the absence of any comparable, currently available text—led us to edit the first edition of *The American Psychiatric Press Textbook of Psychopharmacology,* published in 1995. The response to that edition was overwhelmingly positive. In the second edition, published in 1998, we expanded considerably on the first edition, covering a number of areas in much greater detail, adding several new chapters, and updating all of the previous material. Again, the response was positive. We then presented a third edition in 2004 with virtually all new material, and now this fourth edition has updated the previous material and added several chapters on important (often emerging) areas not previously covered.

In order for the reader to appreciate and integrate the rich amount of information about pharmacological agents, we have attempted in all editions to provide sufficient background material to understand more easily how drugs work and why, when, and in whom they should be used. For this fourth edition, we have updated all the material, often adding new contributors as well as adding several new chapters, and thus expanding the scope and length of the text. The textbook consists of five major parts. The first section, “Principles of Psychopharmacology,” was edited by Robert Malenka and provides a theoretical background for the ensuing parts. It includes chapters on neurotransmitters; signal transduction and second messengers; molecular biology; chemical neuroanatomy; electrophysiology; animal models of psychiatric disorders; psychoneuroendocrinology, pharmacokinetics; and pharmacodynamics; psychoneuroimmunology; brain imaging in psychopharmacology; and statistics/clinical trial design.

The second part, “Classes of Psychiatric Treatments: Animal and Human Pharmacology,” presents information by classes of drugs and is coedited by K. Ranga Rama Krishnan and Dennis Charney. For each drug within a class, data are reviewed on preclinical and clinical pharmacology, pharmacokinetics, indications, dosages, and cognate issues. This section is pharmacopoeia-like. Individual chapters are now generally dedicated to individual agents (e.g., paroxetine, venlafaxine). We include data not only on currently available drugs in the United States but also on medications that will in all likelihood become available in the near future. We have not only updated all the material but invited new authors on many chapters to provide fresh insights.

The third part, “Clinical Psychobiology and Psychiatric Syndromes,” edited by David Kupfer, reviews data on the biological underpinnings of specific disorders—for example, major depression, bipolar disorder, and panic disorder. The chapter authors in this section comprehensively review the biological alterations described for each of the major psychiatric disorders, allowing the reader to better understand current psychopharmacological approaches as well as to anticipate future developments.

The fourth part, “Psychopharmacological Treatment,” edited by David Dunner, reviews state-of-the-art therapeutic approaches to patients with major psychiatric disorders as well as to those in specific age groups or circumstances: childhood disorders, emergency psychiatry, pregnancy and postpartum, and so forth. Here, too, new contributors provide fresh looks at important clinical topics. This section provides the reader with specific information about drug selection and prescription. We have added a new chapter on chronic pain syndromes.

Last, we have added a new chapter on ethical considerations in psychopharmacological treatment and research, providing the reader with a thoughtful overview of this important area.

This textbook would not have been possible without the superb editorial work of the section editors—as well as, of course, the authors of the chapters, who so generously gave of their time. In addition, we wish to thank Editorial Director John McDuffie of American Psychiatric Publishing and his staff for their editorial efforts. In particular, we appreciate the major efforts of Bessie Jones, Acquisitions Coordinator; Greg Kuny, Managing Editor; Tammy J. Cordova, Graphic Design Manager; Susan Westrate, Prepress Coordinator; Judy Castagna, Manufacturing Manager; Melissa Coates, Assistant Editor; and Rebecca Richters, Senior Editor. Finally, we extend our thanks to Tina Coltri-Marshall at the University of California–Davis, Rebecca Wyse at Stanford University, and Janice Dell at Emory University for their invaluable editorial assistance.

Chapter 1. Neurotransmitters, Receptors, Signal Transduction, and Second Messengers in Psychiatric Disorders

NEUROTRANSMITTERS, RECEPTORS, SIGNAL TRANSDUCTION, AND SECOND MESSENGERS IN PSYCHIATRIC DISORDERS: INTRODUCTION

This chapter serves as a primer on the recent advances in our understanding of neural function both in health and in disease. It is beyond the scope of this chapter to cover these important areas in extensive detail, and readers are referred to outstanding textbooks that are entirely devoted to the topic (Cooper et al. 2001; Kandel et al. 2000; Nestler et al. 2001; Squire et al. 2003). Here, we focus on the principles of neurotransmission and second-messenger generation that we believe are critical for an understanding of the biological bases of major psychiatric disorders, as well as the mechanisms by which effective treatments may exert their beneficial effects. In particular, it is our goal to lay the groundwork for the subsequent chapters, which focus on individual disorders and their treatments.

Although this chapter is intended to provide a general overview on neurotransmitter and second-messenger function, whenever possible we emphasize the neuropsychiatric relevance of specific observations. In the chapter proper, we outline principles that are of utmost importance to the study and practice of psychopharmacology; in the figure legends, we provide additional details for the interested reader.

[The work presented in this chapter was undertaken under the auspices of the National Institute of Mental Health Intramural Program. Dr. Manji is now at Johnson & Johnson Pharmaceutical Research & Development.

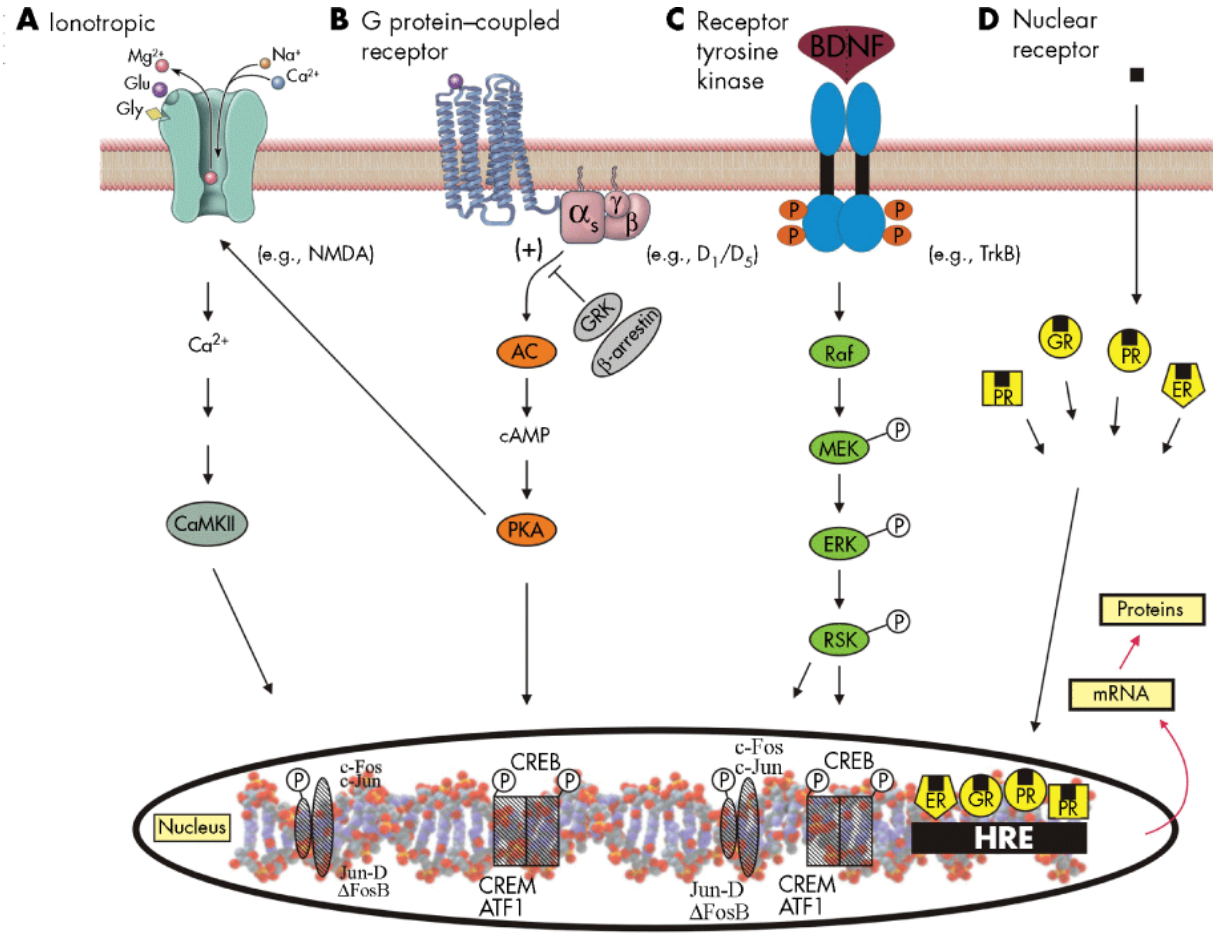
WHAT ARE NEUROTRANSMITTERS?

Several criteria have been established for a neurotransmitter, including 1) it is synthesized and released from neurons; 2) it is released from nerve terminals in a chemically or pharmacologically identifiable form; 3) it interacts with postsynaptic receptors and brings about the same effects as are seen with stimulation of the presynaptic neuron; 4) its interaction with the postsynaptic receptor displays a specific pharmacology; and 5) its actions are terminated by active processes (Kandel et al. 2000; Nestler et al. 2001). However, our growing appreciation of the complexity of the central nervous system (CNS) and of the existence of numerous molecules that exert *neuromodulatory* and *neurohormonal* effects has blurred the classical definition of neurotransmitters somewhat, and even well-known neurotransmitters do not meet all these criteria under certain situations (Cooper et al. 2001).

Most neuroactive compounds are small polar molecules that are synthesized in the CNS via local machinery or are able to permeate the blood–brain barrier. To date, more than 50 endogenous substances have been found to be present in the brain that appear to be capable of functioning as neurotransmitters. There are many plausible explanations for why the brain would need so many transmitters and receptor subtypes to transmit messages. Perhaps the simplest explanation is that the sheer complexity of the CNS results in many afferent nerve terminals impinging on a single neuron. This requires a neuron to be able to distinguish the multiple information conveying inputs. Although this can be accomplished partially by spatial segregation, it is accomplished in large part by chemical coding of the inputs—that is, different chemicals convey different information. Moreover, as we discuss in detail later, the evolution of multiple receptors for a single neurotransmitter means that the same chemical can convey different messages depending on the receptor subtypes it acts on. Additionally, the firing pattern of neurons is also a means of conveying information; thus, the firing activities of neurons in the brain differ widely, and a single neuron firing at different frequencies can even release different neuroactive compounds depending on the firing rate (e.g., the release of peptides often occurs at higher firing rates than that which is required to release monoamines). These multiple mechanisms to enhance the diversity of responses —chemical coding, spatial coding, frequency coding—are undoubtedly critical in endowing the CNS with its complex repertoire of physiological and behavioral responses (Kandel et al. 2000; Nestler et al. 2001). Finally, the existence of multiple neuroactive compounds also provides built-in safeguards to ensure that vital brain circuits are able to partially compensate for loss of function of particular neurotransmitters.



RECEPTORS

An essential property of any living cell is its ability to recognize and respond to external stimuli. Cell surface receptors have two major functions: recognition of specific molecules (neurotransmitters, hormones, growth factors, and even sensory signals) and activation of "effectors." Binding of the appropriate agonist (i.e., neurotransmitter or hormone) externally to the receptor alters the conformation (shape) of the protein. Cell surface receptors use a variety of membrane-transducing mechanisms to transform an agonist's message into cellular responses. In neuronal systems, the most typical responses ultimately (in some cases rapidly, in others more slowly) involve changes in transmembrane voltage and hence neuronal changes in excitability. Collectively, the processes are referred to as *transmembrane signaling* or *signal transduction mechanisms.* These processes are not restricted to neurons. For example, astrocytes, which were once thought to be unrelated to neurotransmission, have recently been demonstrated to possess voltage-regulated anion channels (VRAC), which not only transport Cl^- but also allow efflux of amino acids such as taurine, glutamate, and aspartate (Mulligan and MacVicar 2006).

Interestingly, although increasing numbers of potential neuroactive compounds and receptors continue to be identified, it has become clear that translation of the extracellular signals (into a form that can be interpreted by the complex intracellular enzymatic machinery) is achieved through a relatively small number of cellular mechanisms. Generally speaking, these transmembrane signaling systems, and the receptors that utilize them, can be divided into four major groups (Figure 1–1):

- Those that are relatively self-contained in structure and whose message takes the form of transmembrane ion fluxes **(ionotropic)**
- Those that are multicomponent in nature and generate intracellular second messengers **(G protein–coupled)**
- Those that contain intrinsic enzymatic activity **(receptor tyrosine kinases and phosphatases)**
- Those that are cytoplasmic and translocate to the nucleus to directly regulate transcription (gene expression) after they are activated by lipophilic molecules (often hormones) that enter the cell **(nuclear receptors)**

This figure depicts the four major classes of receptors in the CNS. **(A)** *Ionotropic receptors.* These receptors comprise multiple protein subunits that are combined in such a way as to create a central membrane pore through this complex, allowing the flow of ions. This type of receptor has a very rapid response time (milliseconds). The consequences of receptor stimulation (i.e., excitatory or inhibitory) depend on the types of ions that the receptor specifically allows to enter the cell. Thus, for example, Na^+ entry through the NMDA (*N*-methyl-D-aspartate) receptor depolarizes the neuron and brings about an excitatory response, whereas Cl^- efflux through the γ-aminobutyric acid type A ($GABA_A$) receptor hyperpolarizes the neuron and brings about an inhibitory response. Illustrated here is the NMDA receptor regulating a channel permeable to Ca^{2+}, Na^+, and K^+ ions. The NMDA receptors also have binding sites for glycine, Zn^{2+}, phencyclidine (PCP), MK801/ketamine, and Mg^{2+}; these molecules are able to regulate the function of this receptor. **(B)** *G protein–coupled receptors* (GPCRs). The majority of neurotransmitters, hormones, and even sensory signals mediate their effects via seven transmembrane domain–spanning receptors that are G protein–coupled. The amino terminus of the G protein is on the outside of the cell and plays an important role in the recognition of specific ligands; the third intracellular loop and carboxy terminus of the receptor play an important role in coupling to G proteins and are sites of regulation of receptor function (e.g., by phosphorylation). All G proteins are heterotrimers (consisting of α, β, and γ subunits). The G proteins are attached to the membrane by isoprenoid moieties (fatty acid) via their γ subunits. Compared with the ionotropic receptors, GPCRs mediate a slower response (on the order of seconds). Detailed depiction of the activation of G protein–coupled receptors is given in Figure 1–2. Here we depict a receptor coupled to the G protein G_s (the *s* stands for stimulatory to the enzyme adenylyl cyclase [AC]). Activation of such a receptor produces activation of AC and increases in cAMP levels. G protein–coupled pathways exhibit major amplification properties, and, for example, in model systems researchers have demonstrated a 10,000-fold amplification of the original signal. The effects of cAMP are mediated largely by activation of protein kinase A (PKA). One major downstream target of PKA is CREB (cAMP response element–binding protein), which may be important to the mechanism of action of antidepressants. **(C)** *Receptor tyrosine kinases.* These receptors are activated by neurotrophic factors and are able to bring about acute changes in synaptic function, as well as long-term effects on neuronal growth and survival. These receptors contain intrinsic tyrosine kinase activity. Binding of the ligand triggers receptor dimerization and transphosphorylation of tyrosine residues in its cytoplasmic domain, which then recruits cytoplasmic signaling and scaffolding proteins. The recruitment of effector molecules generally occurs via interaction of proteins with modular binding domains SH2 and SH3 (named after homology to the src oncogenes–src homology domains); SH2 domains are a stretch of about 100 amino acids that allows high-affinity interactions with certain phosphotyrosine motifs. The ability of multiple effectors to interact with phosphotyrosines is undoubtedly one of the keys to the pleiotropic effects that neurotrophins can exert. Shown here is a tyrosine kinase receptor type B (TrkB), which upon activation produces effects on the Raf, MEK (mitogen-activated protein kinase/ERK), extracellular response kinase (ERK), and ribosomal S6 kinase (RSK) signaling pathway. Some major downstream effects of RSK are CREB and stimulation of factors that bind to the AP-1 site (c-Fos and c-Jun). **(D)** *Nuclear receptors.* These receptors are transcription factors that regulate the expression of target genes in response to steroid hormones and other ligands. Many hormones (including glucocorticoids, gonadal steroids, and thyroid hormones) are able to rapidly penetrate into the lipid bilayer membrane, because of their lipophilic composition, and thereby directly interact with these cytoplasmic receptors inside the cell. Upon activation by a hormone, the nuclear receptor–ligand complex translocates to the nucleus, where it binds to specific DNA sequences, referred to as *hormone responsive elements* (HREs), and regulates gene transcription. Nuclear receptors often interact with a variety of coregulators that promote transcriptional activation when recruited (coactivators) and those that attenuate promoter activity (corepressors). However, nongenomic effects of neuroactive steroids have also been documented, with the majority of evidence suggesting modulation of ionotropic receptors. This figure illustrates both the genomic and the nongenomic effects. ATF1 = activation transcription factor 1; BDNF = brain-derived neurotrophic factor; CaMKII = Ca^{2+}/calmodulin–dependent protein kinase II; CREM = cyclic adenosine 5'-monophosphate response element modulator; D_1 = dopamine$_1$ receptor; D_5 = dopamine$_5$ receptor; ER = estrogen receptor; GR = glucocorticoid receptor; GRK = G protein–coupled receptor kinase; P = phosphorylation; PR = progesterone receptor.

Ionotropic Receptors

The first class of receptors contains in their molecular complex an intrinsic *ion channel.* Receptors of this class include those for a number of amino acids, including glutamate (e.g., the NMDA [*N*-methyl-D-aspartate] receptor) and GABA (γ-aminobutyric acid via the $GABA_A$ receptor), as well as the nicotinic acetylcholine (ACh) receptor and the serotonin$_3$ ($5\text{-}HT_3$) receptor. Ion channels are integral membrane proteins that are directly responsible for the electrical activity of the nervous system by virtue of their regulation of the movement of ions across membranes. Receptors containing intrinsic ion channels have been called *ionotropic* and are generally composed of four or five subunits that open transiently when neurotransmitter binds, allowing ions to flow into (e.g., Na^+, Ca^{2+}, Cl^-) or out of (e.g., K^+) the neuron, thereby generating synaptic potential (see Figure 1–1).

Often, the ionotropic receptors can be composed of different compositions of the different subunits, thereby providing the system with considerable flexibility. For example, there is extensive research into the potential development of an anxiolytic that is devoid of sedative effects by targeting $GABA_A$ receptor subunits present in selected brain regions. In general, neurotransmission that is mediated by ionotropic receptors is very fast, with ion channels opening and closing within milliseconds, and regulates much of the tonic excitatory (e.g., glutamate-mediated) and inhibitory (e.g., GABA-mediated) activity in the CNS; as we discuss below, many of the classical neurotransmitters (e.g., monoamines) exert their effects on a slower time scale and are therefore often considered to be modulatory in their effects.

G Protein–Coupled Receptors

Most receptors in the CNS do not have intrinsic ionic conductance channels within their structure but instead regulate cellular activity by the generation of various "second messengers." Receptors of this class do not generally interact directly with the various second-messenger-generating enzymes but instead transmit information to the appropriate "effector" by the activation of interposed coupling proteins. These are the G protein–coupled receptor families. The *G protein–coupled receptors* (GPCRs, which constitute more than 80% of all known receptors in the body, and number about 300) all span the plasma membrane seven times (see Figure 1–1). GPCRs have been the focus of extensive research in psychiatry in recent years (Catapano and Manji 2007). The amino terminus is on the outside of the cell and plays a critical role in recognition of the ligand; the carboxy terminus and third intracellular loop are inside the cell and regulate not only coupling to different G proteins but also "cross talk" between receptors and desensitization (see Figure 1–1).

G proteins are so named because of their ability to bind the guanine nucleotides guanosine triphosphate (GTP) and guanosine diphosphate (GDP). Receptors coupled to G proteins include those for catecholamines, serotonin, ACh, various peptides, and even sensory signals such as light and odorants (Table 1–1). As we discuss later in the chapter, multiple subtypes of G proteins are known to exist, and they play critical roles in amplifying and integrating signals.

TABLE 1–1. Key features of G protein subunits

G protein class	Members	Effector(s)/Functions	Examples of receptors
α_i	$G\alpha_{i1-3}$, $G\alpha_o$	AC (+)	α_2, D_2, A_1, μ, M_2, $5\text{-}HT_{1A}$
		Ligand-type Ca^{2+} channels (+)	Olfactory signals
	$G\alpha_z$, $G\alpha_{t1-2}$	K^+ channels (+)	
		Ca^{2+} channels (–)[a]	$GABA_B$
		Cyclic GMP	Retinal rods, cones (rhodopsins)
		Phosphodiesterase (+) ($G\alpha_{t1-2}$)	
α_q	$G\alpha_q$, $G\alpha_{11}$, $G\alpha_{14}$, $G\alpha_{15}$, $G\alpha_{16}$	PLC-β (+)	TxA_2, $5\text{-}HT_{2C}$, M_1, M_3, M_5, α_1
α_{12}	$G\alpha_{12}$,$G\alpha_{13}$	RGS domain–containing rho exchange factors	TxA_2, thrombin
$\beta\gamma$[b]	β (x5)	AC type I (–); AC types II, IV (potentiation)	
		PLC (+)	
		Receptor kinases (+)	
		Inactivates α_s	
γ	γ (x12)	$\beta\gamma$ required for interaction of α subunit with receptor	

Note. AC = adenylyl cyclase; A_1, A_2 = adenosine receptor subtypes; β_1, α_1, α_2 = adrenergic receptor subtypes; C = cholera toxin; D_1, D_2 = dopamine receptor subtypes; $G\alpha_t$ = olfactory, but also found in limbic areas; $G\alpha_s$ = stimulatory; $G\alpha_t$ = transducin; $GABA_B$ = γ-aminobutyric acid receptor subtype; $5\text{-}HT_{1A}$, $5\text{-}HT_{2C}$ = serotonin receptor subtypes; M_1, M_2, M_3, M_5 = muscarinic receptor subtypes; μ = opioid μ receptor; P = pertussis toxin; PLC = phospholipase C; RGS = regulators of G protein signaling; TxA_2 = thromboxane A_2 receptor.

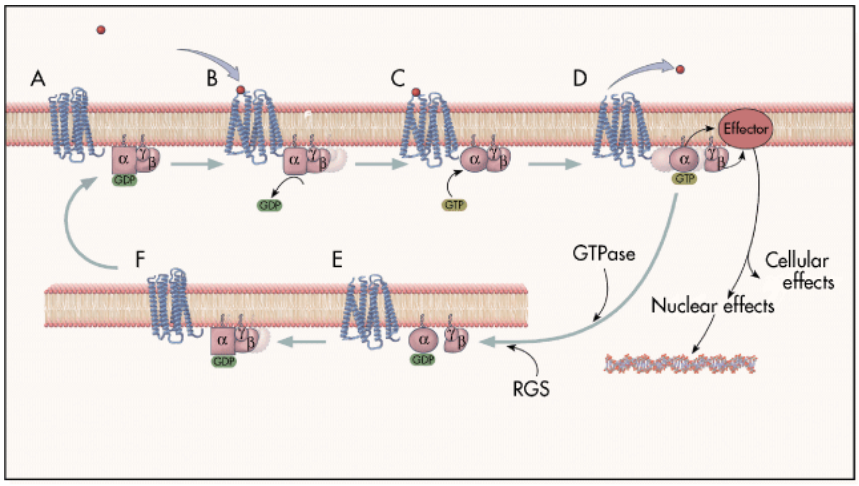
[a]Although regulation of Na^+/H^+ exchange and Ca^{2+} channels by $G\alpha_{1-2}$ and $G\alpha_{1-3}$ has been demonstrated in artificial systems in vitro, these findings await definitive confirmation.

[b]Effectors are regulated by $\beta\gamma$ subunits as a dimer.

Autoreceptors and Heteroreceptors

***Autoreceptors* are receptors located on neurons that produce the endogenous ligand for that particular receptor (e.g., a serotonergic receptor on a serotonergic neuron). By contrast, *heteroreceptors* are receptor subtypes that are present on neurons that do not contain an endogenous ligand for that particular receptor subtype (e.g., a serotonergic receptor located on a dopaminergic neuron).**

Two major classes of autoreceptors play very important roles in fine-tuning neuronal activity. *Somatodendritic autoreceptors* are present on cell bodies and dendrites and exert critical roles in regulating *the firing rate of neurons.* In general, activation of somatodendritic autoreceptors (e.g., α_2-adrenergic receptors for noradrenergic neurons, serotonin1A [$5\text{-}HT_{1A}$] receptors for serotonergic neurons, dopamine$_2$ [D_2] receptors for dopaminergic neurons) inhibits the firing rate of the neurons by opening K^+ channels and by reducing cyclic adenosine monophosphate (cAMP) levels, both of which may be important in psychiatric disease. For example, TREK-1 is a background K^+ channel regulator protein important in 5-HT transmission and potentially in mood-like behavior regulation in mice (Heurteaux et al. 2006). Fundamental mechanisms of neuronal transmission—such as K^+ channels, which regulate membrane potentials—may relate to global alterations in brain functioning relevant to psychiatry.



The second major class of autoreceptors, *nerve terminal autoreceptors,* play an important role in regulating *the amount of neurotransmitter released per nerve impulse,* generally by closing nerve terminal Ca^{2+} channels. Both of these types of autoreceptors are *typically* members of the G protein–coupled receptor family. Neurotransmitter release is known to be triggered by influx and alterations of intracellular calcium, with the functioning of three types of SNARE (soluble *N*-ethylmaleimide–sensitive factor attachment protein [SNAP] receptor) proteins exerting critical roles. Recent advances in our understanding of the distinct kinetics of neurotransmitter release modulators, such as botulinum and tetanus neurotoxins, suggest that these induce prominent alterations in synaptobrevin and syntaxin, leading to calcium-independent mechanisms of neurotransmitter regulation (Sakaba et al. 2005). Most synapses are dependent on influx of Ca^{2+} through voltage-gated calcium channels for presynaptic neurotransmitter release; in the retina, however, this

influx of calcium occurs via glutamatergic AMPA receptors (Chavez et al. 2006). Beyond the receptor level, presynaptic SAD, an intracellular serine threonine kinase, is associated with the active zone cytomatrix that regulates neurotransmitter release (Inoue et al. 2006). These recent data further exemplify the dynamic nature and ongoing advancement of our knowledge pertaining to basic processes involved in neurotransmitter regulation that may possibly aid in advancing treatment of psychopathology.

G Protein–Coupled Receptor Regulation and Trafficking

The mechanism by which GPCRs translate extracellular signals into cellular changes was once envisioned as a simple linear model. It is now known, however, that the activity of GPCRs is subject to at least three additional principal modes of regulation: desensitization, downregulation, and trafficking (Carman and Benovic 1998) (Figure 1–2). *Desensitization,* the process by which cells rapidly adapt to stimulation by agonists, is generally believed to occur by two major mechanisms: homologous and heterologous.

FIGURE 1–2. G protein–coupled receptors and G protein activation.

All G proteins are heterotrimers consisting of α, β, and γ subunits. The receptor shuttles between a low-affinity form that is not coupled to a G protein and a high-affinity form that is coupled to a G protein. **(A)** At rest, G proteins are largely in their inactive state, namely, as αβγ heterotrimers, which have GDP (guanosine diphosphate) bound to the α subunit. **(B)** When a receptor is activated by a neurotransmitter, it undergoes a conformational (shape) change, forming a transient state referred to as a *high-affinity ternary complex,* comprising the agonist, receptor in a high-affinity state, and G protein. A consequence of the receptor interaction with the G protein is that the GDP comes off the G protein α subunit, leaving a very transient empty guanine nucleotide binding domain. **(C)** Guanine nucleotides (generally GTP) quickly bind to this nucleotide binding domain; thus, one of the major consequences of active receptor–G protein interaction is to facilitate guanine nucleotide exchange—this is basically the "on switch" for the G protein cycle. **(D)** A family of GTPase-activating proteins for G protein–coupled receptors has been identified, and they are called regulators of G protein signaling (RGS) proteins. Since activating GTPase activity facilitates the "turn off" reaction, these RGS proteins are involved in dampening the signal. Binding of GTP to the α subunit of G proteins results in subunit dissociation, whereby the α-GTP dissociates from the βγ subunits. Although not covalently bound, the β and γ subunits remain tightly associated and generally function as dimers. The α-GTP and βγ subunits are now able to activate multiple diverse effectors, thereby propagating the signal. While they are in their active states, the G protein subunits can activate multiple effector molecules in a "hit and run" manner; this results in major signal amplification (i.e., one active G protein subunit can activate multiple effector molecules; see Figure 1–11). The activated G protein subunits also dissociate from the receptor, converting the receptor to a low-affinity conformation and facilitating the dissociation of the agonist from the receptor. The agonist can now activate another receptor, and this also results in signal amplification. Together, these processes have been estimated to produce a 10,000-fold amplification of the signal in certain models. **(E)** Interestingly, the α subunit has intrinsic GTPase activity, which cleaves the third phosphate group from GTP (G-P-P-P) to GDP (G-P-P). Since α-GDP is an inactive state, the GTPase activity serves as a built-in timing mechanism, and this is the "turn off" reaction. **(F)** The reassociation of α-GDP with βγ is thermodynamically favored, and the reformation of the inactive heterotrimer (αβγ) completes the G protein cycle.

Homologous desensitization* is receptor specific; that is, only the receptor actively being stimulated becomes desensitized. This form of desensitization occurs via a family of kinases known as G protein–coupled kinases (GRKs). When a receptor activates a G protein and causes dissociation of the α subunit from the βγ subunits (discussed in detail later), the βγ subunits are able to provide an "anchoring surface" for the GRKs to allow them to come into the proximity of the activated receptor and phosphorylate it. This phorphorylation then recruits another family of proteins known as *arrestins,* which physically interfere with the coupling of the phosphorylated receptor and the G protein, thereby dampening the signal. This form of desensitization is very rapid and usually transient (i.e., the receptors get dephosphorylated and return to the baseline state). However, if the stimulation of the receptor is excessive and prolonged, it leads to an internalization of the receptor, and often its degradation, a process referred to as *downregulation.

***Heterologous desensitization* is not receptor specific and is mediated by second-messenger kinases such as protein kinase A (PKA) and protein kinase C (PKC). Thus, when a receptor activates PKA, the activated PKA is capable of phosphorylating (and thereby desensitizing) not only that particular receptor but also other receptors that are present in proximity and have the correct phosphorylation motif, thereby producing heterologous desensitization.**

Upon prolonged or repeated activation of receptors by agonist ligands, the process of receptor *downregulation* is observed. Downregulation is associated with a reduced number of receptors detected in cells or tissues, thereby leading to attenuation of cellular responses (Carman and Benovic 1998). The process of GPCR sequestration is mediated by a well-characterized endocytic pathway involving the concentration of receptors in clathrin-coated pits and subsequent internalization and recycling back to the plasma membrane (Tsao and von Zastrow 2000). Endocytosis can thus clearly serve as a primary mechanism to attenuate signaling by rapidly and reversibly removing receptors from the cell surface. However, emerging evidence suggests additional functions of endocytosis and receptor trafficking in mediating GPCR signaling by way of certain effector pathways, most notably mitogen-activated protein (MAP) kinase cascades (discussed in greater detail later). There is also evidence that endocytosis of GPCRs may be required for certain signal transduction pathways leading to the nucleus (Tsao and von Zastrow 2000). These diverse functions of GPCR endocytosis and trafficking are leading to unexpected insights into the biochemical and functional properties of endocytic vesicles. Indeed, there is considerable excitement about our growing understanding of the diverse molecular mechanisms for signaling specificity and receptor trafficking, and the possibility that this knowledge could lead to highly selective therapeutics.

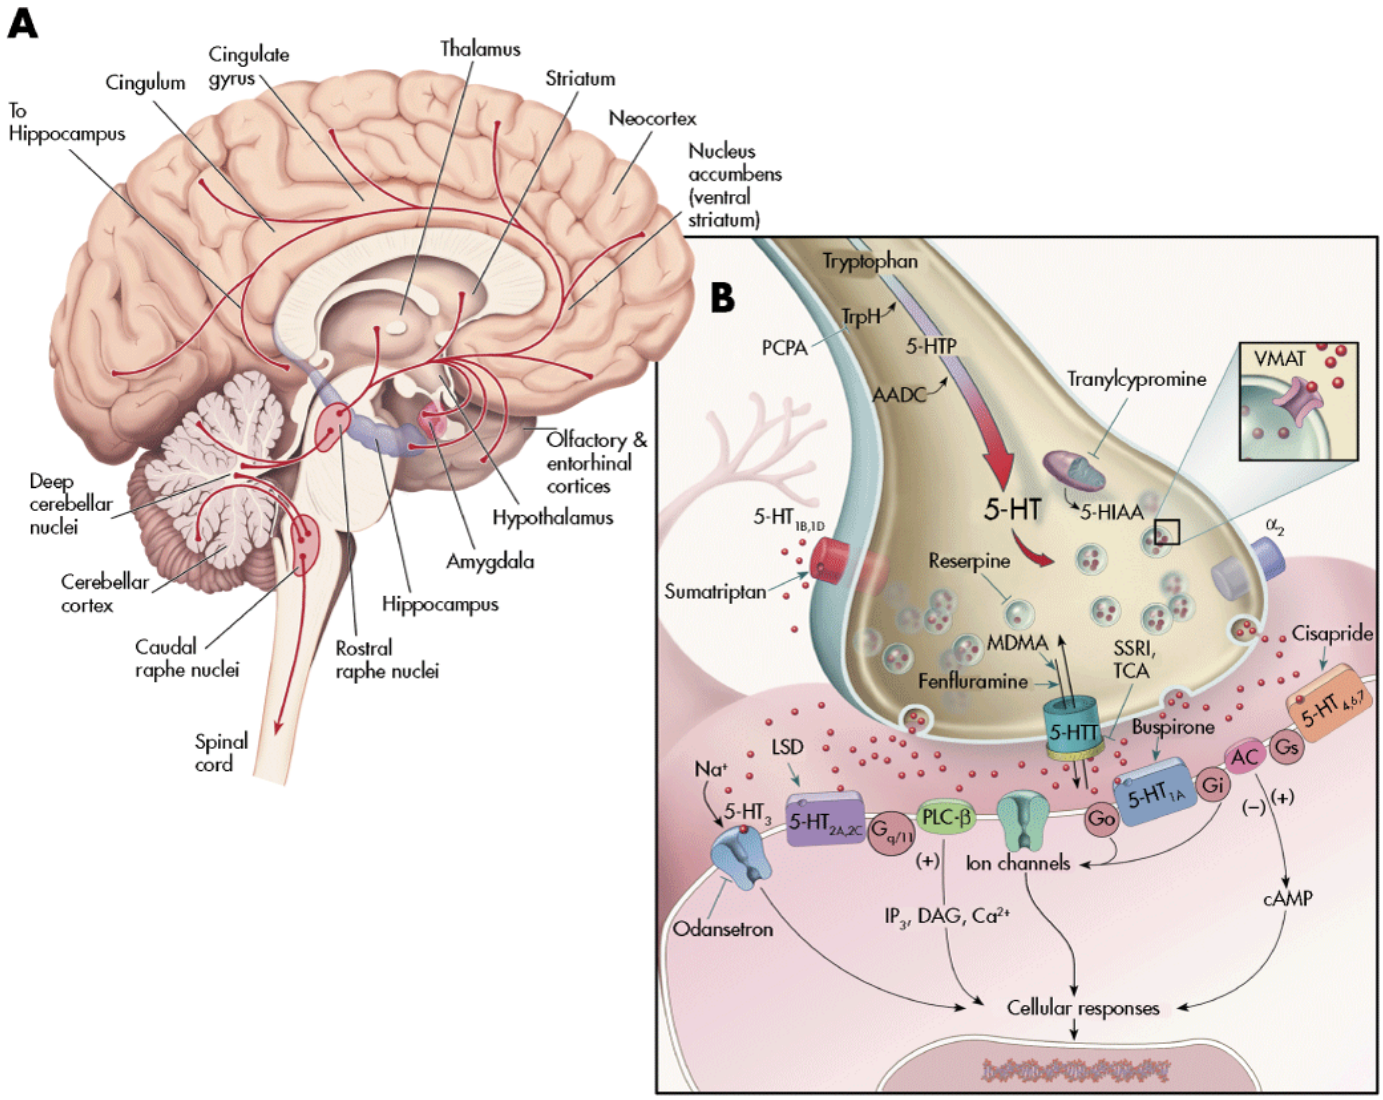
Receptor Tyrosine Kinases

The receptor tyrosine kinases, as their name implies, contain intrinsic tyrosine kinase activity and are generally utilized by growth factors, such as neurotrophic factors, and cytokines. Binding of an agonist initiates receptor dimerization and transphosphorylation of tyrosine residues in its cytoplasmic domain (Patapoutian and Reichardt 2001) (see Figure 1–1). The phosphotyrosine residues of the receptor function as binding sites for recruiting specific cytoplasmic signaling and scaffolding proteins. The ability of multiple effectors to interact with phosphotyrosines is undoubtedly one of the keys to the pleiotropic effects that neurotrophins can exert. These pleiotropic and yet distinct effects of growth factors are mediated by varying degrees of activation of three major signaling pathways: the MAP kinase pathway, the phosphoinositide-3 (PI_3) kinase pathway, and the phospholipase C (PLC)–γ1 pathway (see Figure 1–9 later in this chapter).

Nuclear Receptors

Nuclear receptors are transcription factors that regulate the expression of target genes in response to steroid hormones and other ligands. Many hormones (including glucocorticoids, gonadal steroids, and thyroid hormones) are able to rapidly penetrate into the lipid bilayer membrane, because of their lipophilic composition, and thereby directly interact with these cytoplasmic receptors inside the cell (see Figure 1–1). Upon activation by a hormone, the nuclear receptor–ligand complex translocates to the nucleus, where it binds to specific DNA sequences referred to as *hormone-responsive elements* (HREs), and subsequently regulates gene transcription (Mangelsdorf et al. 1995; Truss and Beato 1993). Nuclear receptors often interact with a variety of coregulators that promote transcriptional activation when recruited *(coactivators)* and those that attenuate promoter activity *(corepressors).*

With this overview of neurotransmitters and receptor subtypes, we now turn to a discussion of selected individual neurotransmitters and neuropeptides before discussing the intricacies of cellular signal transduction systems.



NEUROTRANSMITTER AND NEUROPEPTIDE SYSTEMS

Serotonergic System

Largely on the basis of the observation that most current effective antidepressants and antipsychotics target these systems, the monoaminergic systems (e.g., serotonin, norepinephrine, dopamine) have been extensively studied. Serotonin (5-HT) was given that name because of its activity as an endogenous vasoconstrictor in blood serum (Rapport et al. 1947). It was later acknowledged as being the same molecule (secretin) found in the intestinal mucosa and that is "secreted" by chromaffin cells (Brodie 1900). Following these findings, 5-HT soon became characterized as being a neurotransmitter in the CNS (Bogdansky et al. 1956).

5-HT-producing cell bodies in the brain are localized in the central gray, in the surrounding reticular formation, and in cell clusters located in the center, and thus the name *raphe* (from Latin, meaning midline) was adopted (Figure 1–3A) (discussed more extensively in Chapter 4, "Chemical Neuroanatomy of the Primate Brain"). The dorsal raphe (DR), the largest brain stem 5-HT nucleus, contains approximately 50% of the total 5-HT neurons in the mammalian CNS; in contrast, the medial raphe (MR) comprises 5% (Descarries et al. 1982; Wiklund and Bjorklund 1980). Serotonergic neurons project widely throughout the CNS rather than to discrete anatomical locations (as the dopaminergic neurons appear to do; see Figure 1–4A later in this chapter), leading to the suggestion that 5-HT exerts a major *modulatory* role throughout the CNS (Reader 1980). Interestingly, evidence suggests that infralimbic and prelimbic regions of the ventral medial prefrontal cortex (mPFCv) in rats are responsible for detecting whether a stressor is under the organism's control. When a stressor is controllable, stress-induced activation of the dorsal raphe nucleus is inhibited by the mPFCv, and the behavioral sequelae of the uncontrollable stress response are blocked (Amat et al. 2005). The organism's ability to regulate 5-HT neuron activity and function has been a major ongoing focus of psychiatric disorder research and treatments.

This figure depicts the location of the major serotonin (5-HT)–producing cells (raphe nuclei) innervating brain structures **(A),** and various cellular regulatory processes involved in serotonergic neurotransmission **(B).** 5-HT neurons project widely throughout the CNS and innervate virtually every part of the neuroaxis. L-Tryptophan, an amino acid actively transported into presynaptic 5-HT-containing terminals, is the precursor for 5-HT. It is converted to 5-hydroxytryptophan (5-HTP) by the rate-limiting enzyme tryptophan hydroxylase (TrpH). This enzyme is effectively inhibited by the drug *p*-chlorophenylalanine (PCPA). Aromatic amino acid decarboxylase (AADC) converts 5-HTP to 5-HT. Once released from the presynaptic terminal, 5-HT can interact with a variety (15 different types) of presynaptic and postsynaptic receptors. Presynaptic regulation of 5-HT neuron firing activity and release occurs through somatodendritic 5-HT_{1A} (not shown) and $5\text{-HT}_{1B,1D}$ autoreceptors, respectively, located on nerve terminals. Sumatriptan is a $5\text{-HT}_{1B,1D}$ receptor agonist. (The antimigraine effects of this agent are likely mediated by local activation of this receptor subtype on blood vessels, which results in their constriction.) Buspirone is a partial 5-HT_{1A} agonist that activates both pre- and postsynaptic receptors. Cisapride is a preferential 5-HT_4 receptor agonist that is used to treat irritable bowel syndrome as well as nausea associated with antidepressants. The binding of 5-HT to G protein receptors (G_o, G_i, etc.) that are coupled to adenylyl cyclase (AC) and phospholipase C–β (PLC-β) will result in the production of a cascade of second-messenger and cellular effects. Lysergic acid diethylamide (LSD) likely interacts with numerous 5-HT receptors to mediate its effects. Pharmacologically this ligand is often used as a 5-HT_2 receptor agonist in receptor binding experiments. Ondansetron is a 5-HT_3 receptor antagonist that is marketed as an antiemetic agent for chemotherapy patients but is also given to counteract side effects produced by antidepressants in some patients. 5-HT has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron through 5-HT transporters (5-HTT). Once inside the neuron, it can either be repackaged into vesicles for reuse or undergo enzymatic catabolism. The selective 5-HT reuptake inhibitors (SSRIs) and older-generation tricyclic antidepressants (TCAs) are able to interfere/block the reuptake of 5-HT. 5-HT is then metabolized to 5-hydroxyindoleacetic acid (5-HIAA) by monoamine oxidase (MAO), located on the outer membrane of mitochondria or sequestered and stored in secretory vesicles by vesicle monoamine transporters (VMATs). Reserpine causes a depletion of 5-HT in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this agent). Tranylcypromine is an MAO inhibitor (MAOI) and an effective antidepressant. Fenfluramine (an anorectic agent) and MDMA ("Ecstasy") are able to facilitate 5-HT release by altering 5-HTT function. DAG = diacylglycerol; 5-HTT = serotonin transporter; IP_3 = inositol-1,4,5-triphosphate.

FIGURE 1–4. The dopaminergic system.

This figure depicts the dopaminergic projections throughout the brain **(A)** and various regulatory processes involved in dopaminergic neurotransmission **(B)**. The amino acid L-tyrosine is actively transported into presynaptic dopamine (DA) nerve terminals, where it is ultimately converted into DA. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase (TH). α-Methyl-*p*-tyrosine (AMPT) is a competitive inhibitor of tyrosine hydroxylase and has been used to assess the impact of reduced catecholaminergic function in clinical studies. The production of DA requires that L-aromatic amino acid decarboxylase (AADC) act on L-dopa. Thus, the administration of L-dopa to patients with Parkinson's disease bypasses the rate-limiting step and is able to produce DA quite readily. DA has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron through DA transporters (DATs). DA is then metabolized to dihydroxyphenylalanine (DOPAC) by intraneuronal monoamine oxidase (MAO; preferentially by the MAO-B subtype) located on the outer membrane of mitochondria, or is sequestered and stored in secretory vesicles by vesicle monoamine transporters (VMATs). Reserpine causes a depletion of DA in vesicles by interfering and irreversibly damaging uptake and storage mechanisms. γ-Hydroxybutyrate inhibits the release of DA by blocking impulse propagation in DA neurons. Pargyline inhibits MAO and may have efficacy in treating parkinsonian symptoms by augmenting DA levels through inhibition of DA catabolism. Other clinically used inhibitors of MAO are nonselective and thus likely elevate the levels of DA, norepinephrine, and serotonin. Once released from the presynaptic terminal (because of an action potential and calcium influx), DA can interact with five different G protein–coupled receptors (D_1–D_5), which belong to either the D_1 or D_2 receptor family. Presynaptic regulation of DA neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal D_2 autoreceptors, respectively. Pramipexole is a D_2/D_3 receptor agonist and has been documented to have efficacy as an augmentation strategy in cases of treatment-resistant depression and in the management of Parkinson's disease. The binding of DA to G protein receptors (G_o, G_i, etc.) positively or negatively coupled to adenylyl cyclase (AC) results in the activation or inhibition of this enzyme, respectively, and the production of a cascade of second-messenger and cellular effects (see diagram). Apomorphine is a D_1/D_2 receptor agonist that has been used clinically to aid in the treatment of Parkinson's disease. (SKF-82958 is a pharmacologically selective D_1 receptor agonist.) SCH-23390 is a D_1/D_5 receptor antagonist. There are likely physiological differences between D_1 and D_5 receptors, but the current unavailability of selective pharmacological agents has precluded an adequate differentiation thus far. Haloperidol is a D_2 receptor antagonist, and clozapine is a nonspecific D_2/D_4 receptor antagonist (both are effective antipsychotic agents). Once inside the neuron, DA can either be repackaged into vesicles for reuse or undergo enzymatic catabolism. Nomifensine is able to interfere/block the reuptake of DA. The antidepressant bupropion has affinity for the dopaminergic system, but it is not known whether this agent mediates its effects through DA or possibly by augmenting other monoamines. DA can be degraded to homovanillic acid (HVA) through the sequential action of catechol-*O*-methyltransferase (COMT) and MAO. Tropolone is an inhibitor of COMT. Evidence suggests that the COMT gene may be linked to schizophrenia (Akil et al. 2003).

The precursor for 5-HT synthesis is l-tryptophan, an amino acid that comes primarily from the diet and crosses the blood–brain barrier through a carrier for large neutral amino acids. Tryptophan hydroxylase (TrpH) is the rate-limiting enzyme in serotonin biosynthesis (Figure 1–3B), and polymorphisms in this

enzyme have been extensively investigated in psychiatric disorders, with equivocal results to date. A more fruitful research strategy in humans has been tryptophan depletion via dietary restriction to study the role of serotonin in the pathophysiology and treatment of psychiatric disorders (Bell et al. 2001). These studies have indicated that tryptophan depletion produces a rapid depressive relapse in patients treated with selective serotonin reuptake inhibitors (SSRIs) but not in those treated with norepinephrine reuptake inhibitors; the data suggesting induction of depressive symptoms in remitted patients or individuals with family histories of mood disorders are more equivocal (Bell et al. 2001).

Serotonin Transporters

As is the case for many classical neurotransmitters, termination of the effects of 5-HT in the synaptic cleft is brought about in large part by an active reuptake process mediated by the 5-HT transporter (5-HTT). 5-HT is taken up into the presynaptic terminals, where it is metabolized by the enzyme monoamine oxidase (MAO) or sequestered into secretory vesicles by the vesicle monoamine transporter (see Figure 1–3B). This presumably underlies the mechanism by which MAO inhibitors initiate their therapeutic effects; that is, the blockade of monoamine breakdown results in increasing the available pool for release when an action potential invades the nerve terminal. It is now well established that many tricyclic antidepressants and SSRIs exert their initial primary pharmacological effects by binding to the 5-HTT and blocking 5-HT reuptake, thereby increasing the intrasynaptic levels of 5-HT, which initiates a cascade of downstream effects (see Figure 1–3B for details). It has been hypothesized that the first step in 5-HT transport involves the binding of 5-HT to the 5-HTT and then a cotransport with Na^+, while the second step involves the translocation of K^+ across the membrane to the outside of the cell. SSRIs bind to the same site on the transporter as 5-HT itself. Recently, elegant biochemical and mutagenesis experiments have elucidated a leucine transporter from bacterial species, providing information that may aid in unraveling the complex process by which mammalian transporters couple ions and substrates to mediate neurotransmitter clearance (Henry et al. 2006).

In the brain, 5-HTTs have been radiolabeled with [^{3}H]-imipramine (Hrdina et al. 1985; Langer et al. 1980) and with SSRIs such as [^{3}H]cyanoimipramine (Wolf and Bobik 1988), [^{3}H]paroxetine (Habert et al. 1985), and [^{3}H]citalopram (D'Amato et al. 1987). The regional distribution of 5-HTT corresponds to discrete regions of rat brain known to contain cell bodies of 5-HT neurons and synaptic axon terminals, most notably the cerebral cortex, neostriatum, thalamus, and limbic areas (Cooper et al. 2001; Hrdina et al. 1990; Madden 2002). The specific cellular localization of 5-HTT in the CNS has also been accomplished by using site-specific antibodies (Lawrence et al. 1995a). Immunohistochemical studies utilizing antibodies against the 5-HT carrier have revealed both neuronal and glial staining in areas of the rat brain containing 5-HT somata and terminals (i.e., DR and hippocampus) (Lawrence et al. 1995b). Experimental alterations of 5-HTT in young mice for a brief period during early development indicate abnormal emotional behavior in the same mice later in life, similar to the phenotype in mice where 5-HTT is deficient throughout life (Ansorge et al. 2004). This suggests the necessity of 5-HT early in emotional development and provides a possible mechanism by which genetic changes in the 5-HTT system may lead to susceptibility to developing psychiatric diseases such as depression (Caspi et al. 2003). Furthermore, 5-HT uptake ability has been documented in primary astrocyte cultures (Kimelberg and Katz 1985) and has been postulated to account for considerable 5-HT uptake in the frontal cortex and periventricular region (Ravid et al. 1992). Since 5-HTT is transcribed from a single copy gene, abnormalities in platelet 5-HTT have been postulated to reflect CNS abnormalities (Owens and Nemeroff 1998). A number of studies on platelet 5-HTT density have been undertaken using [3H]imipramine binding or [3H]paroxetine binding in mood disorders. Although the results of these studies are not entirely consistent, in toto the results suggest that the B_{max} value for platelet 5-HT density is significantly lower in depressed subjects compared with healthy control subjects (Owens and Nemeroff 1998).

Serotonin Receptors

In 1957, the existence of two separate 5-HT receptors was first proposed primarily because of the opposing phenomenon this neurotransmitter produces in reference to cholinergic mediation of smooth muscle contraction (Gaddum and Picarelli 1957). Today, through the use of more precise molecular cloning and pharmacological and biochemical studies, seven distinct 5-HT receptor families have been identified (5-HT_{1-7}), many of which contain several subtypes. With the exception of the 5-HT_3 receptor, which is an excitatory ionotropic receptor, all the other 5-HT receptors are GPCRs. The 5-$HT_{1A,B,D,E,F}$ receptors are negatively coupled to adenylyl cyclase, the 5-$HT_{2A,B,C}$ subtypes are positively coupled to PLC, and the 5-HT_4, 5-HT_5, 5-HT_6, and 5-HT_7 subtypes are positively coupled to adenylyl cyclase (see Figure 1–3B) (Humphrey et al. 1993).

5-HT_1 receptors

5-HT_{1A} receptors are found in particularly high density in several limbic structures, including the hippocampus, septum, amygdala, and entorhinal cortex, as well as on serotonergic neuron cell bodies, where they serve as autoreceptors regulating 5-HT neuronal firing rates (Blier et al. 1998; Cooper et al. 2001; Pazos and Palacios 1985). The highest density of labeling is found in the DR, with lower densities observed in the remaining raphe nuclei (Pazos and Palacios 1985). The density and mRNA expression of 5-HT_{1A} receptors appear insensitive to reductions in 5-HT transmission associated with lesioning the raphe or administering the serotonin-depleting agent *p*-chlorophenylalanine (PCPA). Similarly, elevation of 5-HT transmission resulting from chronic administration of an SSRI or monoamine oxidase inhibitor (MAOI) does not consistently alter 5-HT_{1A} receptor density or mRNA in the cortex, hippocampus, amygdala, or hypothalamus. In contrast to the insensitivity to 5-HT, 5-HT_{1A} receptor density is downregulated by adrenal steroids. Postsynaptic 5-HT_{1A} receptor gene expression is under tonic inhibition by adrenal steroids in the hippocampus and some other regions. Thus, in rodents, hippocampal 5-HT_{1A} receptor mRNA expression is increased by adrenalectomy and decreased by corticosterone administration or chronic stress. The stress-induced downregulation of 5-HT_{1A} receptor expression is prevented by adrenalectomy. Mineralocorticoid receptor stimulation has the most potent effect on downregulating 5-HT_{1A} receptors, although glucocorticoid receptor stimulation also contributes to this effect.

In addition to being expressed on neurons, postsynaptic 5-HT_{1A} receptors are also abundantly expressed by astrocytes and some other glia (Whitaker-Azmitia et al. 1990) (see Figure 1–7 later in this chapter). Stimulation of astrocyte-based 5-HT_{1A} sites causes astrocytes to acquire a more mature morphology and to release the trophic factor S-100β, which promotes growth and arborization of serotonergic axons. Administration of 5-HT_{1A} receptor antagonists, antibodies to S-100β, or agents that deplete 5-HT produces similar losses of dendrites, spines, and/or synapses in adult and developing animals—effects that are blocked by administration of 5-HT_{1A} receptor agonists or SSRIs. These observations have led to the hypothesis that a reduction of 5-HT_{1A} receptor function may play an important role in mood disorders that are known to be associated with glial reductions (Manji et al. 2001). The use of conditional knockouts of the 5-HT_{1A} receptor, in which gene expression is altered only in particular anatomical regions and/or during particular times, has illustrated the caution necessary in attributing complex behaviors to simple "too much" or "too little" neurotransmitter/receptor hypotheses. Using a knockout/rescue approach with regional and temporal specificity, Gross et al. (2002) demonstrated that the anxiety-related effect of the 5-HT_{1A} receptor knockout was actually developmental. Specifically, expression limited to the hippocampus and cortex during early postnatal development was sufficient to counteract the anxious phenotype of the mutant, even though the receptor was still absent in adulthood (Gross et al. 2002). As is discussed in the chapters on antidepressants and axiolytics (see Chapters 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, and 26), there is growing interest in the observation that antidepressants enhance hippocampal neurogenesis (Duman 2002; Malberg et al. 2000). It is noteworthy that preliminary data suggest that 5-HT_{1A} receptor activation is required for SSRI-induced hippocampal neurogenesis in mice (Jacobs et al. 2000). Altering 5-HT levels with the SSRI fluoxetine does not affect division of stem cells in the dentate gyrus, but rather increases symmetric divisions of an early progenitor cell class that exists after stem cell division (Encinas et al. 2006).

5-HT_{1A} receptors are now known to utilize a variety of signaling mechanisms to bring about their effects in distinct brain areas. Thus, somatodendritic 5-HT_{1A} receptors appear to inhibit the firing of serotonergic neurons by opening a K^+ channel through a pertussis toxin–sensitive G protein (likely G_o, discussed later in the section on G proteins) (Andrade et al. 1986), as well as by reducing cAMP levels. Postsynaptic 5-HT_{1A} receptors appear to exert many of their effects by inhibiting adenylyl cyclase via G_i (De Vivo and Maayani 1990) but have also been demonstrated to potentiate the activity of certain

adenylyl cyclases (Bourne and Nicoll 1993) and to stimulate inositol-1,4,5-triphosphate (IP_3) production and activate PKC (Y. F. Liu and Albert 1991).

5-HT_{1D} receptors are virtually absent in the rodent but have been detected in guinea pig and man (Bruinvels et al. 1993). On the basis of an approximately 74% sequence homology, it has been proposed that 5-HT_{1B} receptors are the rodent homolog of 5-HT_{1D} receptors (see Saxena et al. 1998). Furthermore, the distribution of the 5-HT_{1D} receptors in guinea pig and man is roughly equivalent to that of the 5-HT_{1B} receptors in the rat (Bruinvels et al. 1993). Both 5-HT_{1B} and 5-HT_{1D} receptors have been proposed to represent the major nerve terminal autoreceptors regulating the amount of 5-HT released per nerve impulse (Pineyro and Blier 1999) (see Figure 1–3B). Like 5-HT_{1A} receptors, 5-HT_{1B} and 5-HT_{1D} receptors inhibit cAMP formation and stimulate IP_3 production and activate PKC (Schoeffter and Bobirnac 1995). As we discuss later, this appears to be the case for many receptors coupled to G_i and G_o (see Table 1–1). The α subunits of the G protein (α_i and α_o) inhibit adenylyl cyclase and regulate ion channels, respectively, whereas the $\beta\gamma$ subunits activate PLC isozymes to stimulate IP_3 production and activate PKC.

Finally, it should be noted that the 5-HT_{1C} receptor classification has been revoked, as these receptors have structural and transductional similarities to the 5-HT_2 receptor class (Hoyer et al. 1986; Saxena et al. 1998).

5-HT_2 receptors

There are three subtypes of 5-HT_2 receptors: 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}. The highest level of 5-HT_{2A} binding sites and mRNA for these receptors exists in the cortex, and these receptors have been implicated in the psychotomimetic effects of agents like lysergic acid diethylamide (LSD) (for a review, see Aghajanian and Marek 1999). In addition, lesioning of 5-HT neurons with 5,7-DHT does not reduce the 5-HT_2 receptor density reported in brain regions (Hoyer et al. 1986), indicating that these receptors are primarily (if not exclusively) postsynaptic. Autoradiography performed with the potent and selective radioligand [^{3}H]MDL 100,907 has localized 5-HT_{2A} receptors to many similar brain regions in the rat and primate brain (Lopez-Gimenez et al. 1997). Recent experiments show that mice expressing 5-HT_{2A} receptors only in the frontal cortex have conserved receptor signaling and behavioral responses to hallucinogenic drugs similar to those of wild-type littermates, suggestive of cortical importance (Gonzalez-Maeso et al. 2007). Competition studies with other radioligands (Westphal and Sanders-Bush 1994) and their mRNA distribution indicate that 5-HT_{2C} receptors are considerably widespread throughout the CNS, with the highest density in the choroid plexus (Hoffman and Mezey 1989). 5-HT_{2B} receptors are detected sparingly in the brain and are more prominently located in the fundus, gut, kidney, lungs, and heart (Hoyer et al. 1986).

Several antidepressants (e.g., mianserin, mirtazapine) and antipsychotics (e.g., clozapine) bind to 5-HT_2 receptors, raising the possibility that blockade of 5-HT_2 receptors may play an important role in the therapeutic efficacy of these agents. Indeed, a leading hypothesis concerning the mechanism of action of atypical antipsychotic agents suggests that the ratio of D_2/5-HT_2 blockade confers "atypicality" properties on many currently available antipsychotic agents (Meltzer 2002). Evidence from animal experiments in which cortical 5-HT_{2A} receptors are disrupted indicates a specific role of these receptors in modulation of conflict anxiety without affecting fear conditioning and depression-like behaviors (Weisstaub et al. 2006). Furthermore, chronic administration of many antidepressants downregulates 5-HT_2 receptors, suggesting that this effect may be important for their efficacy (J. A. Scott and Crews 1986); however, chronic electroconvulsive shock (ECS) appears to upregulate 5-HT_2 expression, precluding a simple mechanism for antidepressant efficacy. The obesity seen in 5-HT_{2C} knockout animals suggests that in addition to histamine receptor blockade, 5-HT_{2C} blockade may play a role in the weight gain observed with certain psychotropic agents; this is an area of considerable current research. In keeping, recent evidence suggests that the weight gain "orexigenic" properties of atypical antipsychotics are likely due to potent activation of hypothalamic AMP-kinase through histamine$_1$ (H_1) receptors (Kim et al. 2007). The regulation of 5-HT_2 receptors is intriguing, as not only is it important in psychiatric disorders and therapeutic benefit, but both agonists and antagonists appear to cause an internalization of the receptor. Moreover, emerging data suggest that mRNA editing may play an important role in regulating the levels and activity of this receptor subtype (Niswender et al. 1998). All of the 5-HT_2 receptor subtypes are linked to the phosphoinositide signaling system, and their activation produces IP_3 and diacylglycerol (DAG), via PLC activation (Conn and Sanders-Bush 1987) (see Figure 1–3B).

An exciting recent pharmacogenetic investigation searched for genetic predictors of treatment outcome in 1,953 patients with major depressive disorder who were treated with the antidepressant citalopram in the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study and prospectively assessed (McMahon et al. 2006). In a split-sample design, a selection of 68 candidate genes was genotyped, with 768 single-nucleotide-polymorphism markers chosen to detect common genetic variation. A significant and reproducible association was detected between treatment outcome and a marker in HTR2A ($P = 1 \times 10^{-6}$ to 3.7×10^{-5} in the total sample). The "A" allele (associated with better outcome) was six times more frequent in white than in black participants, for whom treatment was also less effective in this sample (McMahon et al. 2006). The "A" allele may thus contribute to racial differences in outcomes of antidepressant treatment. Taken together with prior neurobiological findings, these new genetic data make a compelling case for a key role of HTR2A in the mechanism of antidepressant action.

5-HT_{3-7} receptors

Unlike the other 5-HT receptors, 5-HT_3 receptors are ligand-gated ion channels capable of mediating fast synaptic responses (see Figure 1–3B). The cis-trans isomerization and molecular rearrangement at proline 8 is the structural mechanism that opens the 5-HT_3 receptor protein pore (Lummis et al. 2005). 5-HT_3 receptors are present in multiple brain areas, including the hippocampus, dorsal motor nucleus of the solitary tract, and area postrema (Laporte et al. 1992). The 5-HT_3 receptor is effectively modulated by a variety of compounds, such as alcohols and anesthetics, and antagonists against this receptor are used as effective antiemetics in patients who are undergoing chemotherapy (e.g., ondansetron). 5-HT_4, 5-HT_6, and 5-HT_7 are GPCRs that are preferentially coupled to Gs and activate adenylyl cyclases (see Figure 1–3B). 5-HT_4 receptors are able to modulate the release of monoamines and GABA in the brain. 5-HT_5 receptors are located in the hypothalamus, hippocampus, corpus callosum, cerebral ventricles, and glia (Hoyer et al. 2002). The 5-HT_{5A} receptor is negatively coupled to adenylyl cyclase, whereas the 5-HT_{5B} receptor does not involve cAMP accumulation or phosphoinositide turnover. 5-HT_6 receptors are located in the striatum, amygdala, nucleus accumbens, hippocampus, cortex, and olfactory tubercle (Hoyer et al. 2002). Of interest, many antipsychotic agents and antidepressants have high affinity for 5-HT_6 receptors and act as antagonists at this receptor. 5-HT_7 receptors have been localized to the cerebral cortex, medial thalamic nuclei, substantia nigra, central gray, and dorsal raphe nucleus (Hoyer et al. 2002). It appears that chronic treatment with antidepressants is able to downregulate this receptor, whereas acute stress has been reported to alter 5-HT_7 expression (Sleight et al. 1995; Yau et al. 2001).

Dopaminergic System

Dopamine (DA) was originally thought to simply be a precursor of norepinephrine (NE) and epinephrine synthesis, but the demonstration that its distribution in the brain was quite distinct to that of NE led to extensive research demonstrating its role as a unique critical neurotransmitter. DA synthesis requires transport of the amino acid L-tyrosine across the blood–brain barrier and into the cell. Once tyrosine enters the neuron, the rate-limiting step for DA synthesis is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase (TH); L-dopa is readily converted to dopamine and, hence, is used as a precursor strategy to correct a dopamine deficiency in the treatment of Parkinson's disease (Figure 1–4B). The activity of TH can be regulated by many factors, including the activity of catecholamine neurons; furthermore, catecholamines function as end-product inhibitors of TH by competing with a tetrahydrobiopterin cofactor (Cooper et al. 2001).

In contrast to the widespread 5-HT and NE projections, DA neurons form more discrete circuits, with the nigrostriatal, mesolimbic, tuberoinfundibular, and tuberohypophysial pathways comprising the major CNS dopaminergic circuits (Figure 1–4A). The nigrostriatal circuit is composed of DA neurons from the mesencephalic reticular formation (region A8) and the pars compacta region of the substantia nigra (region A9) of the mesencephalon. These neurons give

rise to axons that travel via the medial forebrain bundle to innervate the caudate nucleus and putamen (see Anden et al. 1964; Ungerstedt 1971). The DA neurons that make up the nigrostriatal circuit have been assumed to be critical for maintaining normal motor control, since destruction of these neurons is associated with Parkinson's disease; however, it is now clear that these projections subserve a variety of additional functions. For example, recent evidence from human brain imaging studies indicates that a subject's ability to choose rewarding actions during instrumental learning tasks can be modulated by administration of drugs that enhance or reduce striatal DA receptor activation. This further implies that the DA reward pathway in the brain is likely convergent on many discrete brain circuits and neurotransmitter alterations, and it shows that striatal activity can also account for how the human brain proceeds toward making future decisions based on reward prediction (Pessiglione et al. 2006).

The mesolimbic DA circuit consists of DA neurons located in the midbrain just medial to the A9 cells in an area termed the ventral tegmental area (VTA) (Cooper et al. 2001; Nestler et al. 2001; Squire et al. 2003). This circuit shares some similarities to the nigrostriatal circuit in that it is a parallel circuit consisting of axons that make up the medial forebrain bundle. However, these axons ascend through the lateral hypothalamus and project to the nucleus accumbens, olfactory tubercle, bed nucleus of the stria terminalis, lateral septum, and frontal, cingulate, and entorhinal regions of the cerebral cortex (Cooper et al. 2001). This circuit innervates many limbic structures known to play critical roles in motivational, motor, and reward pathways and has therefore been implicated in a variety of clinical conditions, including psychosis and drug abuse (Cooper et al. 2001). Data also suggest a potential role for dopamine—and, in particular, mesolimbic pathways—in the pathophysiology of bipolar mania as well as bipolar and unipolar depression (Beaulieu et al. 2004; Dunlop and Nemeroff 2007; Goodwin and Jamison 2007; Roybal et al. 2007). It is perhaps surprising that the role of the dopaminergic system in the pathophysiology of mood disorders has not received greater study, since it represents a prime candidate on a number of theoretical grounds. The motoric changes in bipolar disorder are perhaps the most defining characteristics of the illness, ranging from the near-catatonic immobility of depressive states to the profound hyperactivity of manic states. Similarly, loss of motivation is one of the central features of depression, whereas anhedonia and "hyperhedonic states" are among the most defining characteristics of bipolar depression and mania, respectively. In this context, it is noteworthy that the midbrain dopaminergic system is known to play a critical role in regulating not only motoric activity but also motivational and reward circuits. It is clear that motivation and motor function are closely linked and that motivational variables can influence motor output both qualitatively and quantitatively. Furthermore, there is considerable evidence that the mesolimbic dopaminergic pathway plays a crucial role in the selection and orchestration of goal-directed behaviors, particularly those elicited by incentive stimuli (Goodwin and Jamison 2007).

The firing pattern of mesolimbic DA neurons appears to be an important regulatory mechanism; thus, in rats, electrical or glutamatergic stimulation of medial prefrontal cortex elicits a burst firing pattern of dopaminergic cells in the VTA and increases DA release in the nucleus accumbens (Murase et al. 1993; Taber and Fibiger 1993). The burst firing of DA cell activity elicits more terminal DA release per action potential than the nonbursting pacemaker firing pattern (Roth et al. 1987). The phasic burst firing of DA neurons and accompanying rise in DA release normally occur in response to primary rewards (until they become fully predicted) and reward-predicting stimuli. Such a role has also been postulated to provide a neural mechanism by which prefrontal cortex dysfunction could alter hedonic perceptions and motivated behavior in mood disorders (Drevets et al. 2002). Recent studies indicate that the amygdala is important in learning new cocaine drug-seeking responses as well as the habit-forming properties of cocaine (Lee et al. 2005), expanding our knowledge of drug addiction circuits in the brain.

Dopamine Transporters

As with serotonin, the DA signal in the synaptic cleft is terminated primarily by reuptake into the presynaptic terminal. The dopamine transporter (DAT) comprises 12 putative transmembrane domains and is located somatodendritically as well as on DA nerve terminals (see Figure 1–4B). Like other monoamine transporters, the DAT functions as a Na^+/K^+ pump to clear DA from the synaptic cleft upon its release. However, data suggest that many drugs of abuse are capable of altering the function of these transporters. Thus, the amphetamines are thought to mediate their effects, in part, by reversing the direction of the transporter so that it *releases* DA. Cocaine is capable of blocking the reuptake of DAT, leading to an increase in DA in the synaptic cleft. Of interest, altered neuronal long-term potentiation in the VTA in response to chronic cocaine exposure has been recently linked to drug-associated memory and likely contributes to the powerful addictive potential of this drug of abuse (Q. S. Liu et al. 2005). DA in the medial frontal cortex is taken up predominantly by the NE transporter. Although the precise functional significance of this finding is not currently known, it goes against the dogma of transporters being able to selectively take up only their respective neurotransmitter. Furthermore, this provides a mechanism by which NE reuptake–inhibiting antidepressants may also increase synaptic levels of DA in the frontal cortex, effects that may be therapeutically very important.

Dopaminergic Receptors

The existence of two subtypes of DA receptors, dopamine$_1$ (D_1) and dopamine$_2$ (D_2), was initially established using classic pharmacological techniques in the 1970s (Stoof and Kebabian 1984). Subsequent molecular biological studies have shown that the D_1 family contains both the D_1 and dopamine$_5$ (D_5) receptors, whereas the D_2 family contains the D_2, dopamine$_3$ (D_3), and dopamine$_4$ (D_4) receptors (Cooper et al. 2001). D_1 receptor family members were originally defined solely on the ability to stimulate adenylyl cyclase (AC), while the D_2 family inhibited the enzyme. Interestingly, DA receptors complexed with subunits from other subclasses of DA receptors within a receptor family are able to form distinct hetero-oligomeric receptors (also termed "kissing cousin receptors"). Notably, hetero-oligomeric D_1–D_2 receptor complexes in the brain require binding to active sites of both receptor subtypes to induce activation of the hetero-oligomeric receptor complex. These receptors have been demonstrated to use traditional D_1 receptor intracellular signaling components of $G_{q/11}$ and Ca^{2+}/calmodulin–dependent protein kinase II (CaMKII) second-messenger activation as demonstrated in the nucleus accumbens (Rashid et al. 2007). This work suggests possible avenues through which the brain might use different receptor subunit proportions to further fine-tune brain neurophysiology.

D_1 and D_5 receptors

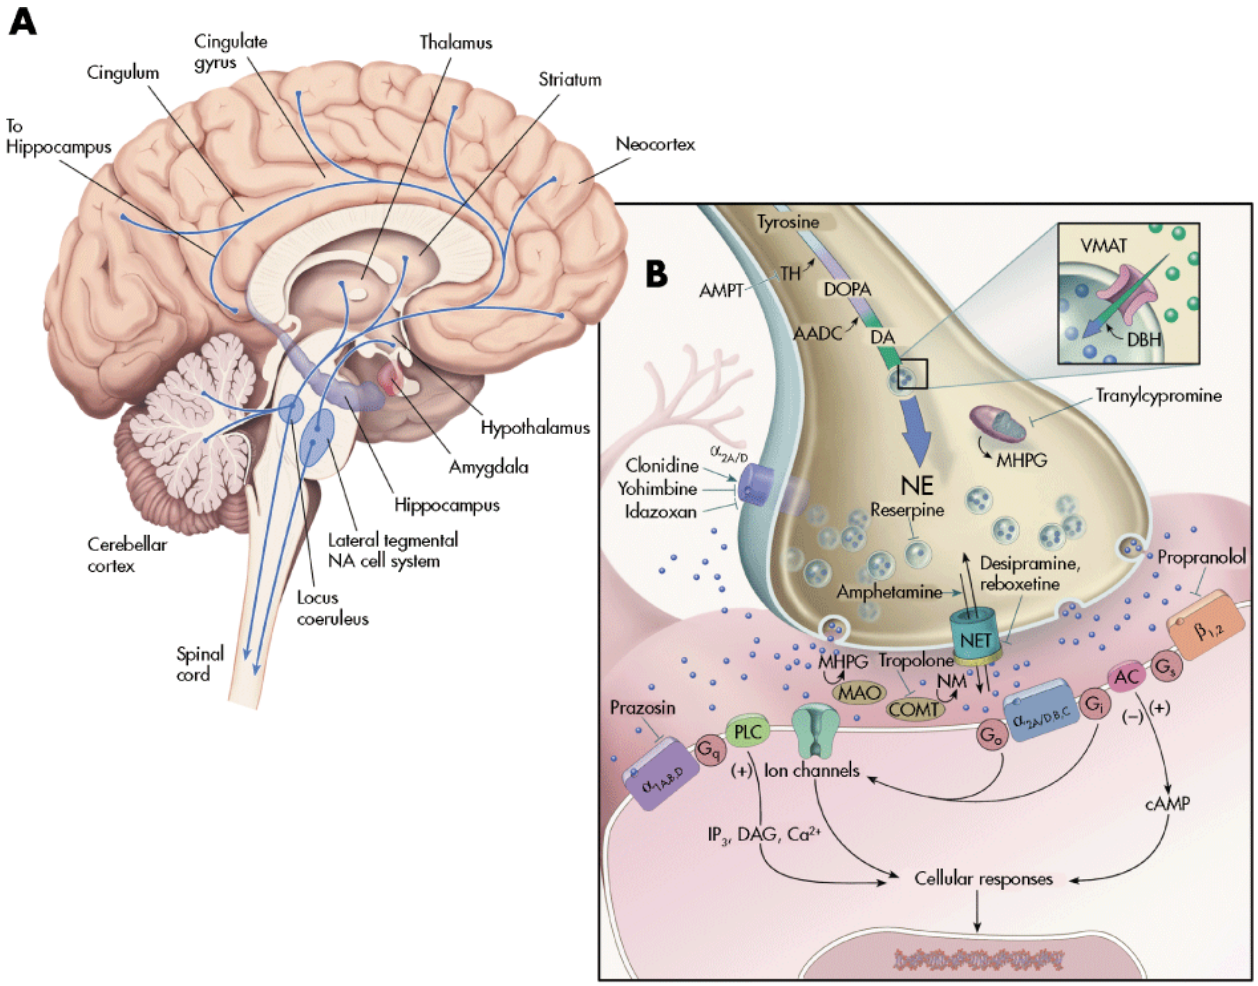
The D_1 and D_5 receptors stimulate adenylyl cyclase activity via the activation of G_s or G_{olf} (a G protein originally thought to be present exclusively in olfactory tissue but now known to be abundantly present in limbic areas) (see Figure 1–4B). Other second-messenger pathways have also been reported to be activated by D_1 receptors, effects that may play a role in the reported D_1–D_2 cross-talk (Clark and White 1987). The frontal cortex contains almost exclusively D_1 receptors (Clark and White 1987), suggesting that this receptor may play an important role in higher cognitive function and perhaps in the actions of medications like methylphenidate. The D_5 receptor is a neuron-specific receptor that is located primarily in limbic areas of the brain.

D_2 receptors

Four types of D_2 receptors have been identified. The two subtypes of D_2 receptors (the short and long forms, D_{2S} and D_{2L}, respectively) are derived from alternative splicing of the D_2 gene. Although a seemingly identical pharmacological profile for these receptors exists, there are undoubtedly (yet to be discovered) physiological differences between the two subtypes. D_2 receptors mediate their cellular effects via the G_i/G_o proteins and thereby several effectors (see Figure 1–4B). In addition to the well-characterized inhibition of adenylyl cyclase, D_2 receptors in different brain areas also regulate PLC, bring changes in K^+ and Ca^{2+} currents, and possibly regulate phospholipase A_2. D_2 receptors are located on cell bodies and nerve terminals of DA neurons and function as autoreceptors. Thus, activation of somatodendritic D_2 receptors reduces DA neuron firing activity, likely via opening of K^+ channels, whereas activation of nerve-terminal D_2 autoreceptors reduces the amount of DA released per nerve impulse, in large part by closing voltage-gated Ca^{2+} channels. As discussed extensively in Chapters 27 and 46, D_2 receptors have long been implicated in the pathophysiology and treatment of schizophrenia. Recently, transgenic mice overexpressing D_2 receptors in the striatum have been found to display many phenotypic hallmarks of schizophrenia (Kellendonk et al. 2006).

D_3 receptors

D_3 receptors possess a different anatomical distribution than do D_2 receptors and, because of their preferential limbic expression, have been postulated to represent an important target for antipsychotic drugs. Numerous studies have investigated the position association of a polymorphism in the coding sequence of the D_3 receptor with schizophrenia, with equivocal results. It has been suggested that brain-derived neurotrophic factor (BDNF) may regulate behavioral sensitization via its effects on D_3 receptor expression (Guillin et al. 2001).



D_4 receptors

The D_4 receptor has received much interest in psychopharmacological research in recent years because of the fact that clozapine has a high affinity for this receptor. Studies are currently underway that are investigating more selective D_4 antagonists as adjunctive agents in the treatment of schizophrenia. Furthermore, considerable attention has focused on the possibility that genetic D_4 variants may be associated with thrill-seeking behavior (Zuckerman 1985), attention-deficit/hyperactivity disorder (Roman et al. 2001), and responsiveness to clozapine (Van Tol et al. 1992).

Noradrenergic System

Named *sympathine* because it was initially encountered as being released by sympathetic nerve terminals, the molecule was later given the name *norepinephrine* after meeting the criteria for a neurotransmitter in the CNS (see Cooper et al. 2001). NE is produced from the amino acid precursor L-tyrosine found in neurons in the brain, chromaffin cells, sympathetic nerves, and ganglia. The enzyme dopamine β-hydroxylase (DBH) converts DA to NE, and as is the case for DA synthesis, tyrosine hydroxylase is the rate-limiting enzyme for NE synthesis (Figure 1–5B). The dietary depletion of tyrosine and α-methyl-*p*-tyrosine (a TH inhibitor) has played an important part in efforts aimed at delineating the role of catecholamines in the pathophysiology and treatment of mood and anxiety disorders (Coupland et al. 2001; McCann et al. 1995).

This figure depicts the noradrenergic projections throughout the brain **(A)** and the various regulatory processes involved in norepinephrine (NE) neurotransmission **(B).** NE neurons innervate nearly all parts of the neuroaxis, with neurons in the locus coeruleus being responsible for most of the NE in the brain (90% of NE in the forebrain and 70% of total NE in the brain). The amino acid L-tyrosine is actively transported into presynaptic NE nerve terminals, where it is ultimately converted into NE. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase (TH). α-Methyl-*p*-tyrosine (AMPT) is a competitive inhibitor of tyrosine hydroxylase and has been used to assess the impact of reduced catecholaminergic function in clinical studies. Aromatic amino acid decarboxylase (AADC) converts L-dopa to dopamine (DA). L-dopa then becomes decarboxylated by decarboxylase to form dopamine (DA). DA is then taken up from the cytoplasm into vesicles, by vesicle monoamine transporters (VMATs), and hydroxylated by dopamine β-hydroxylase (DBH) in the presence of O_2 and ascorbate to form NE. Normetanephrine (NM), which is formed by the action of COMT (catechol-*O*-methyltransferase) on NE, can be further metabolized by monoamine oxidase (MAO) and aldehyde reductase to 3-methoxy-4-hydroxyphenylglycol (MHPG). Reserpine causes a depletion of NE in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this hypertension). Once released from the presynaptic terminal, NE can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of NE neuron firing activity and release occurs through somatodendritic (not shown) and nerve-terminal α_2 adrenoreceptors, respectively. Yohimbine potentiates

NE neuronal firing and NE release by blocking these α_2 adrenoreceptors, thereby disinhibiting these neurons from a negative feedback influence. Conversely, clonidine attenuates NE neuron firing and release by activating these receptors. Idazoxan is a relatively selective α_2 adrenoreceptor antagonist primarily used for pharmacological purposes. The binding of NE to G protein receptors (G_o, G_i, etc.) that are coupled to adenylyl cyclase (AC) and phospholipase C–β (PLC-b) produces a cascade of second-messenger and cellular effects (see diagram and later sections of the text). NE has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron via NE transporters (NETs). Once inside the neuron, it can either be repackaged into vesicles for reuse or undergo enzymatic degradation. The selective NE reuptake inhibitor and antidepressant reboxetine and older-generation tricyclic antidepressant desipramine are able to interfere/block the reuptake of NE. On the other hand, amphetamine is able to facilitate NE release by altering NET function. Green spheres represent DA neurotransmitters; blue spheres represent NE neurotransmitters. DAG = diacylglycerol; IP_3 = inositol-1,4,5-triphosphate.

There are seven NE cell groups in the mammalian CNS, designated A1 through A7. In the brain stem, these are the lateral tegmental neurons (A5 and A7) and the locus coeruleus (A6) (Dahlstrom 1971) (see Figure 1–5B). In general, the projections from A5 and A7 are more restricted to brain stem areas and do not interact with those of A6. The term *locus coeruleus* (LC) was derived from the Greek because of its saddle shape and its "bluish color" *(caeruleum).* The LC is the most widely projecting CNS nucleus known (Foote et al. 1983), responsible for approximately 90% of the NE innervation of the forebrain and 70% of the total NE in the brain (Figure 1–5A). Indeed, the LC NE neurons, although small in number, constitute a diffuse system of projections to widespread brain areas via highly branched axons. The extensive efferent innervation suggests that the LC plays a modulatory and integrative role, rather than a role in specific sensory or motor processing (Foote et al. 1983).

A number of physiological roles have been ascribed to the LC, notably in the control of vigilance and the initiation of adaptive behavioral responses (Foote et al. 1983). Considerable data support the hypothesis that NE neurons in the LC constitute a CNS response or defense system, since the neurons are activated by "challenges" in both the behavioral/environmental and the physiological domains (Jacobs et al. 1991). Thus, while a variety of sensory stimuli are capable of increasing LC activity, noxious or stressful stimuli are particularly potent in this regard. Moreover, considerable evidence also supports a role for LC NE neurons in the learning of aversively motivated tasks and in the conditioned response to stressful stimuli (Rasmussen et al. 1986a, 1986b), with obvious implications for a variety of psychiatric conditions (see Gould et al. 2003; Szabo and Blier 2001). Indeed, tonic activation of the LC appears to occur preferentially in the response to stressful stimuli, in contrast to stimuli limited to simply evoking activation or arousal (Rasmussen et al. 1986a, 1986b).

Norepinephrine Transporter

The norepinephrine transporter (NET), the first of the monoamine transporters to be cloned in humans, transports NE from the synaptic cleft back into the neuron (Pacholczyk et al. 1991). Like other monoamine transporters, NET comprises 12 putative transmembrane domains, and autoradiography with various NE reuptake inhibitors has been used to determine the brain distribution of NET. A high level of NET is found in the LC, with moderate to high levels found in the dentate gyrus, raphe nuclei, and hippocampus (Tejani-Butt and Ordway 1992; Tejani-Butt et al. 1990). This pattern of expression is consistent with the NE innervation to these structures. The NET is expressed mainly on NE terminals, as demonstrated by a drastic reduction in labeling following NE destruction with the neurotoxin 6-hydroxydopamine or DSP-4 (Tejani-Butt and Ordway 1992; Tejani-Butt et al. 1990).

The NET is dependent on extracellular Na^+ to mediate NE reuptake and the effectiveness of NE reuptake inhibitors in inhibiting NE reuptake (Bruss et al. 1997, 1999; Harder and Bonisch 1985). The uptake of NE is Cl^- dependent, meaning that the electrogenic process of NE transport is Na^+ and Cl^- driven (Harder and Bonisch 1985). In addition to the electrogenic process, the NET demonstrates properties of a channel-like pore, in that it can transport NE showing an infinite stoichiometry that can be blocked by cocaine and desipramine (Galli et al. 1995, 1996). A number of studies suggest that NET can be regulated by diverse stimuli, neuronal activity, and peptide hormones, as well as protein kinases. Indeed, studies have shown that all monoaminergic transporters (5-HTT, DAT, and NET) are rapidly regulated by direct or receptor-mediated activation of cellular kinases, particularly PKC (Bauman et al. 2000). PKC activation results in an activity-dependent transporter phosphorylation and sequestration. Protein phosphatase–1/2A (PP-1/PP-2A) inhibitors, such as okadaic acid and calyculin A, also promote monoaminergic transporter phosphorylation and functional downregulation (Bauman et al. 2000). These phenomena that occur beyond the receptor level may well be important in the long-term actions of psychotropic drugs known to regulate protein kinases (G. Chen et al. 1999; Manji and Lenox 1999).

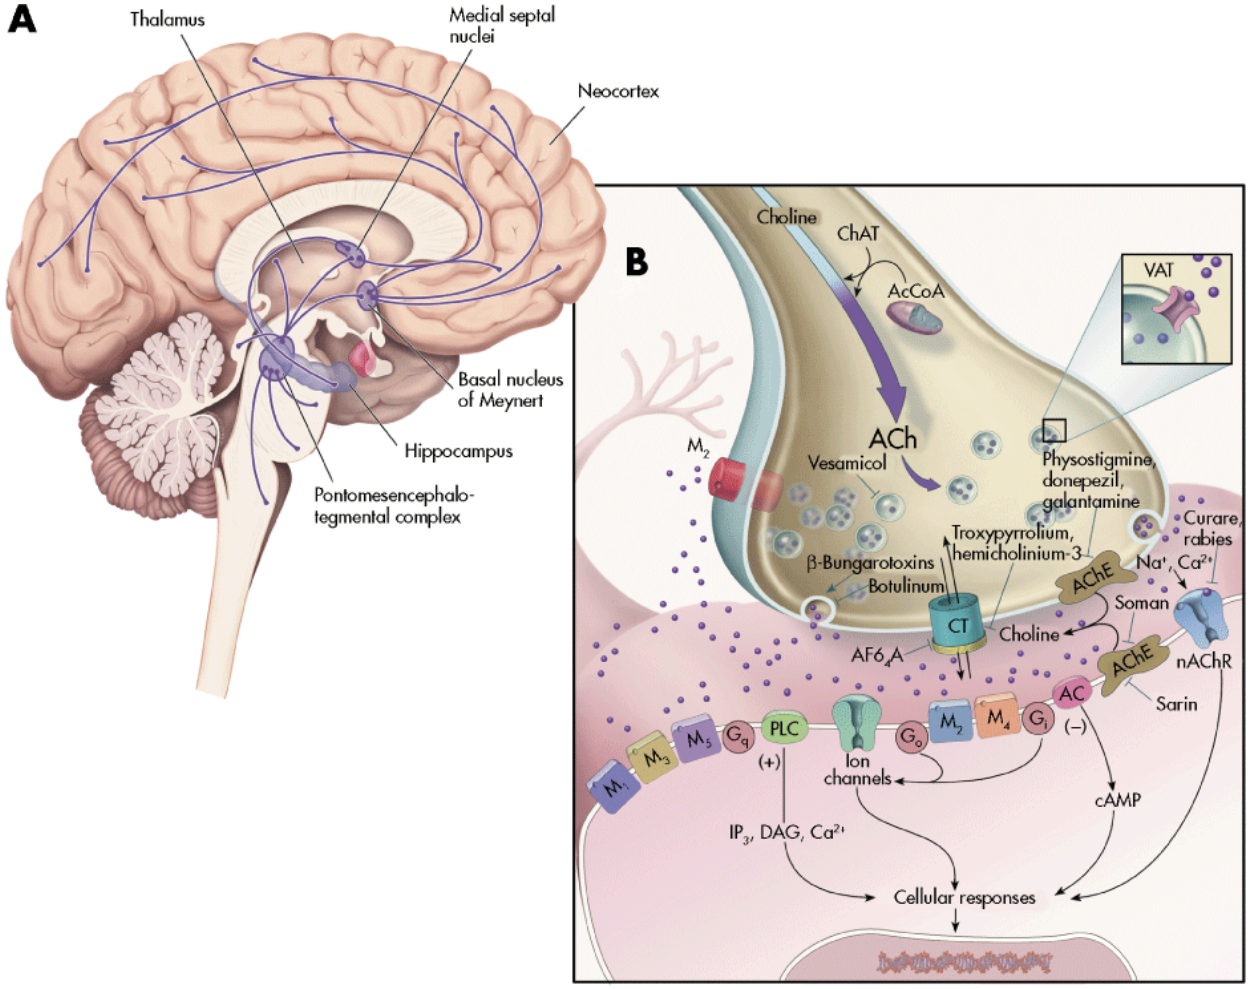
Adrenergic Receptors

The α and β catecholamine receptors were first discovered more than 50 years ago (Alhquist 1948) and later subdivided further into α_1, α_2, and β_1, β_2, and β_3 adrenoreceptors—all of which are GPCRs—on the basis of molecular cloning and pharmacological and biochemical studies (see Figure 1–5B).

α receptors

There are three subtypes of α_1 receptors, denoted 1A, 1B, and 1D; they are all positively coupled to PLC and possibly phospholipase A_2 (see Figure 1–5B). The α_2 family comprises the 2A/D, 2B, and 2C subtypes, which couple negatively to adenylyl cyclase and regulate K^+ and Ca^{2+} channels (see Figure 1–5B). The 2A, 2B, and 2C adrenoceptors correspond to the human genes α_2-*C10,* α_2-*C2,* and α_2-*C4,* respectively (see Bylund et al. 1994). The bovine, guinea pig, rat, and mouse a_{2D} adrenoreceptor is thought to be a species homolog or variant of the human α_{2A} adrenoreceptor (Bylund et al. 1994) and is often referred to as $\alpha_{2A/D}$. The α_2 receptors represent autoreceptors for NE neurons, and blockade of these autoreceptors results in increased NE release—a biochemical effect that has been postulated to play a role in the mechanisms of action of selected antidepressants (e.g., mianserin, mirtazapine) and antipsychotics (e.g., clozapine). In the LC, α_2-adrenergic receptors converge onto similar K^+ channels as μ opioid receptors, and this convergence has been postulated to represent a mechanism for the efficacy of clonidine (an α_2 agonist) in attenuating some of the physical symptoms of opioid withdrawal. The α_2 antagonist yohimbine, which robustly increases NE neuron firing and NE release, has been used as a provocative challenge in clinical studies of anxiety disorders and as an antidepressant-potentiating agent. Given that NE neurons colocalize and release orexins, it is of interest that this neuropeptide has been implicated in sleep disorders and hypoglycemia through its glucose-sensing tandem-pore K^+ (K^{2P}) effects in coordinating arousal (M. M. Scott et al. 2006).

β receptors



The β receptor family comprises β_1, β_2, and β_3 adrenoreceptors, which are all positively coupled to adenylyl cyclase (Bylund et al. 1994) (see Figure 1–5B). As is discussed in greater detail in the chapters on antidepressants and anxiolytics (see Chapters 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, and 26), most effective antidepressants produce a downregulation/desensitization of β_1 receptors in rat forebrain, leading to the suggestion that these effects may play a role in their therapeutic efficacy. Interestingly, β receptors have also been shown to play a role in regulating emotional memories, leading to the proposal that β antagonists may have utility in the treatment of posttraumatic stress disorder (PTSD) (Cahill et al. 1994; Przybyslawski et al. 1999). β_3 receptors are not believed to be present in the CNS but are abundantly expressed on brown fat, where they exert lipolytic and thermogenic effects. Not surprisingly, there is active research attempting to develop selective β_3 agonists for the treatment of obesity.

Cholinergic System

ACh is the only major low-molecular-weight neurotransmitter substance that is not derived from an amino acid (Kandel et al. 2000). ACh is synthesized from acetyl coenzyme A and choline in nerve terminals via the enzyme choline acetyltransferase (ChAT). Choline is transported into the brain by uptake from the bloodstream and enters the neuron via both high-affinity and low-affinity transport processes (Cooper et al. 2001). In addition to the "standard"

ChAT pathway, there are several additional possible mechanisms by which ACh can be synthesized; the precise roles of these additional pathways and their physiological relevance in the CNS remain to be fully elucidated (Cooper et al. 2001). The highest activity of ChAT is observed in the interpeduncular nucleus, caudate nucleus, corneal epithelium, retina, and central spinal roots. In contrast to the other transmitters discussed thus far (which are most dependent on reuptake mechanisms), ACh has its signal terminated primarily by the enzyme acetylcholine esterase, which degrades ACh (Figure 1–6B). Not surprisingly, therapeutic strategies to increase synaptic ACh levels (e.g., for the treatment of Alzheimer's disease) have focused on inhibiting the activity of cholinesterases.

This figure depicts the cholinergic pathways in the brain **(A)** and various regulatory processes involved in cholinergic neurotransmission **(B).** Choline crosses the blood–brain barrier to enter the brain and is actively transported into cholinergic presynaptic terminals by an active uptake mechanism (requiring ATP). This neurotransmitter is produced by a single enzymatic reaction in which acetyl coenzyme A (AcCoA) donates its acetyl group to choline by means of the enzyme choline acetyltransferase (ChAT). AcCoA is primarily synthesized in the mitochondria of neurons. Upon its formation, acetylcholine (ACh) is sequestered into secretory vesicles by vesicle ACh transporters (VATs), where it is stored. Vesamicol effectively blocks the transport of ACh into vesicles. An agent such as β-bungarotoxin or $AF64A$ is capable of increasing synaptic concentration of ACh by acting as a releaser and a noncompetitive reuptake inhibitor, respectively. In turn, agents such as botulinum toxin are able to attenuate ACh release from nerve terminals. Once released from the presynaptic terminals, ACh can interact with a variety of presynaptic and postsynaptic receptors. In contrast to many other monoaminergic neurotransmitters, the ACh signal is terminated primarily by degradation by the enzyme acetylcholinesterase (AChE) rather than by reuptake. Interestingly, AChE is present on both presynaptic and postsynaptic membranes and can be inhibited by physostigmine (reversible) and soman (irreversible). Currently, AChE inhibitors such as donepezil and galantamine are the only classes of agents that are FDA approved for the treatment of Alzheimer's disease. ACh receptors are of two types: muscarinic (G protein–coupled) and nicotinic (ionotropic). Presynaptic regulation of ACh neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal M2 autoreceptors, respectively. The binding of ACh to G protein–coupled muscarinic receptors that are negatively coupled to adenylyl cyclase (AC) or coupled to phosphoinositol hydrolysis produces a cascade of second-messenger and cellular effects (see diagram). ACh also activates ionotropic nicotinic receptors (nAChRs). ACh has it action terminated in the synapse through rapid degradation by AChE, which liberates free choline to be taken back into the presynaptic neuron through choline transporters (CTs). Once inside the neuron, it can be reused for the synthesis of ACh, can be repackaged into vesicles for reuse, or undergoes enzymatic degradation. There are some relatively new agents that selectively antagonize the muscarinic receptors, such as CI-1017 for M_1, methoctramine for M_2, 4-DAMP for M_3, PD-102807 for M_4, and scopolamine (hardly a new agent) for M_5 (although it also has affinity for M3 receptor). nAChR or nicotine receptors are activated by nicotine and the specific alpha(4)beta(2*) agonist metanicotine. Mecamylamine is an AChR antagonist. DAG = diacylglycerol; IP_3 = inositol-1,4,5-triphosphate.

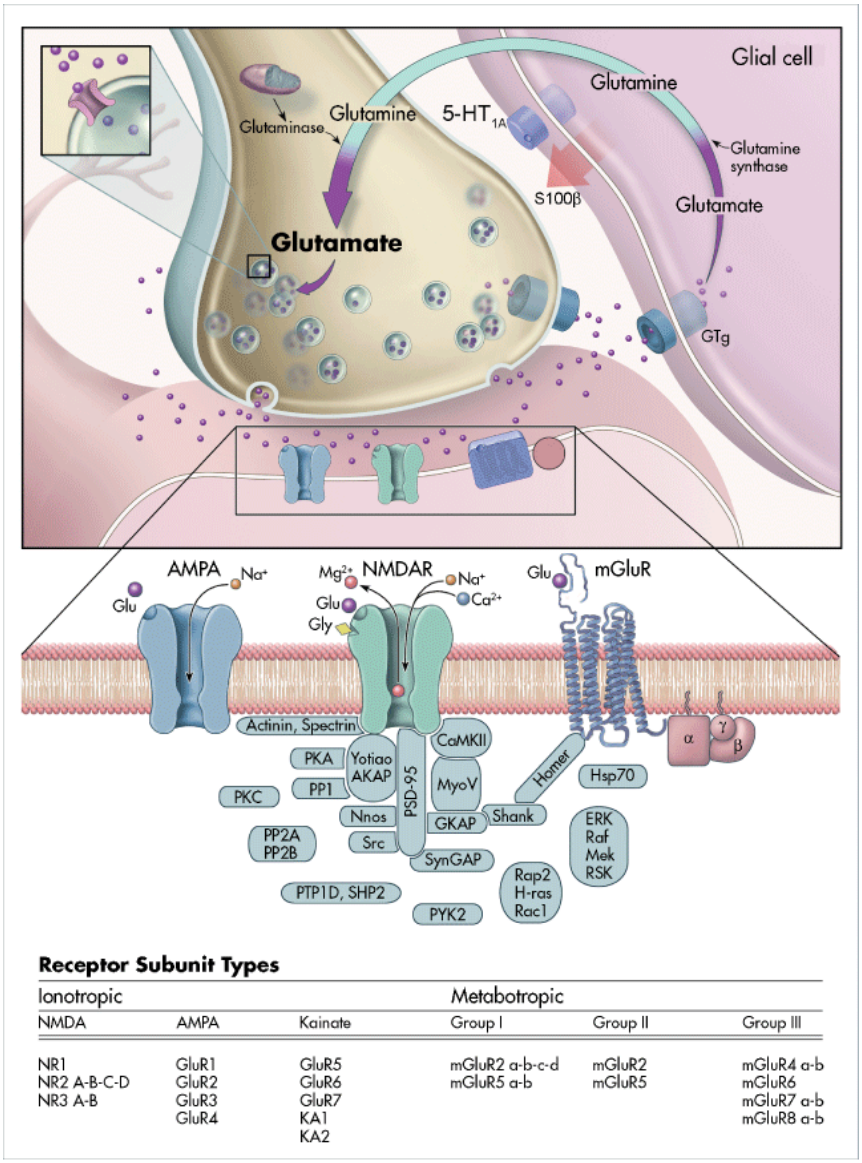
Several cholinergic pathways have been proposed, but until recently the circuits had not been worked out in the brain because of the lack of appropriate techniques. The development of tract tracing and histochemical techniques has provided a clearer picture of the cholinergic pathways. In brief, cholinergic neurons can act as local circuit neurons (interneurons) and are found in the caudate putamen, nucleus accumbens, olfactory tubercle, and islands of Calleja complex (Cooper et al. 2001). They do, however, also serve to function as projection neurons that connect different brain regions; one fairly

well-characterized pathway runs from the septum to the hippocampus (Figure 1–6A). The basal forebrain cholinergic complex is composed of cholinergic neurons originating from the medial septal nucleus, diagonal band nuclei, substantia innominata, magnocellular preoptic field, and nucleus basalis. These nuclei project cholinergic neurons to the entire nonstriatal telencephalon, pontomesencephalotegmental cholinergic complex, thalamus, and other diencephalic loci (see Figure 1–6A). Descending cholinergic projections from these nuclei also innervate pontine and medullary reticular formations, deep cerebellar and vestibular nuclei, and cranial nerve nuclei (Cooper et al. 2001).

Cholinergic Receptors

There are two major distinct classes of cholinergic receptors, the *muscarinic* and *nicotinic* receptors. Five muscarinic receptors (M_1 through M_5) have been cloned (Kandel et al. 2000). These receptors are G protein–coupled and act either by regulating ion channels (in particular, K^+ or Ca^{2+}) or through being linked to second-messenger systems. Generally speaking, M_1, M_3, and M_5 are coupled to phosphoinositol hydrolysis, whereas M_2 and M_4 are coupled to inhibition of adenylyl cyclase and regulation of K^+ and Ca^{2+} channels (Cooper et al. 2001) (see Figure 1–6B).

By contrast, the nicotinic receptors are ionotropic receptors, and at least seven different functional receptors (based on different subunit composition) have been identified. Biochemical and biophysical data indicate that the nicotinic receptors in the muscle are formed from five protein subunits, with the stoichiometry of $\alpha_2\beta\gamma\delta$ (Kandel et al. 2000). The binding of ACh molecules on the α subunit is necessary for channel activation. By contrast, neuronal nicotinic receptors contain only two types of subunits (α and β), with the α occurring in at least seven different forms and the β in three (Cooper et al. 2001). Nicotinic receptors may be the targets of considerable cross-talk, as a variety of kinases (including PKA, PKC, and tyrosine kinases) are able to regulate the sensitivity of this receptor. A number of regulatory mechanisms exist. For example, the mammalian prototoxin lynx1 acts as an allosteric modulator of nicotinic acetylcholine receptors (Miwa et al. 2006).



From a clinical standpoint, Freedman et al. (1997) demonstrated that in a cohort of patients with schizophrenia, abnormal P50 auditory evoked potentials were linked to a susceptibility locus for this disease on chromosome 15. Notably, this is where a nicotinic receptor subunit is found, providing indirect support for the long-standing contention that the high rates of cigarette smoking in patients with schizophrenia may represent (at least in part) an attempt to correct an underlying nicotinic receptor defect.

Glutamatergic System

Glutamate and aspartate are the two major excitatory amino acids in the CNS and are present in high concentrations (Nestler et al. 2001; Squire et al. 2003). As the principal mediators of excitatory synaptic transmission in the mammalian brain, they participate in wide-ranging aspects of both normal and abnormal CNS function. Physiologically, glutamate appears to play a prominent role in synaptic plasticity, learning, and memory. However, glutamate can also be a potent neuronal excitotoxin under a variety of experimental conditions, triggering either rapid or delayed neuronal death. Unlike the monoamines, which require transport of amino acids through the blood–brain barrier, glutamate and aspartate cannot adequately penetrate into the brain from the periphery and are produced locally by specialized brain machinery. The metabolic and synthetic enzymes responsible for the formation of these nonessential amino acids are located in glial cells as well as neurons (Squire et al. 2003).

The major metabolic pathway in the production of glutamate is derived from glucose and the transamination of α-ketoglutarate; however, a small proportion of glutamate is formed directly from glutamine. The latter is actually synthesized in glia, via an active process (requiring adenosine triphosphate [ATP]), and is then transported to neurons where glutaminase is able to convert this precursor to glutamate (Figure 1–7). Following release, the concentration of glutamate in the extracellular space is highly regulated and controlled, primarily by a Na^+-dependent reuptake mechanism involving several transporter proteins.

This figure depicts the various regulatory processes involved in glutamatergic neurotransmission. The biosynthetic pathway for glutamate involves synthesis from glucose and the transamination of α-ketoglutarate; however, a small proportion of glutamate is formed more directly from glutamine by glutamine synthetase. The latter is actually synthesized in glia and, via an active process (requiring ATP), is transported to neurons, where in the mitochondria glutaminase is able to convert this precursor to glutamate. Furthermore, in astrocytes glutamine can undergo oxidation to yield α-ketoglutarate, which can also be transported to neurons and participate in glutamate synthesis. Glutamate is either metabolized or sequestered and stored in secretory vesicles by vesicle glutamate transporters (VGluTs). Glutamate can then be released by a calcium-dependent excitotoxic process. Once released from the presynaptic terminal, glutamate is able to bind to numerous excitatory amino acid (EAA) receptors, including both ionotropic (e.g., NMDA [*N*-methyl-D-aspartate]) and metabotropic (mGluR) receptors. Presynaptic regulation of glutamate release occurs through metabotropic glutamate receptors (mGluR2 and mGluR3), which subserve the function of autoreceptors; however, these receptors are also located on the postsynaptic element. Glutamate has its action terminated in the synapse by reuptake mechanisms utilizing distinct glutamate transporters (labeled VGT in figure) that exist on not only presynaptic nerve terminals but also astrocytes; indeed, current data suggest that astrocytic glutamate uptake may be more important for clearing excess glutamate, raising the possibility that astrocytic loss (as has been documented in mood disorders) may contribute to deleterious glutamate signaling, but more so by astrocytes. It is now known that a number of important intracellular proteins are able to alter the function of glutamate receptors (see diagram). Also, growth factors such as glial-derived neurotrophic factor (GDNF) and S100β secreted from glia have been demonstrated to exert a tremendous influence on glutamatergic neurons and synapse formation. Of note, serotonin$_{1A}$ (5-HT$_{1A}$) receptors have been documented to be regulated by antidepressant agents; this receptor is also able to modulate the release of S100β. The major glutamate transporter proteins found in the CNS include the excitatory amino acid transporters (EAATs) EAAT1 (or GLAST-1), EAAT2 (or GLT-1), and EAAT3 (or EAAC1), with EAAT2 being the most predominantly expressed form in the forebrain. Additionally, these transporters are differentially expressed in specific cell types, with EAAT1 and EAAT2 being found primarily in glial cells and EAAT3 being localized in neurons. EAAT4 is mainly localized in cerebellum. The physiological events regulating the activity of the glutamate transporters are not well understood, although there is evidence that phosphorylation of the transporters by protein kinases may differentially regulate glutamate transporters and therefore glutamate reuptake (Casado et al.

1993; Conradt and Stoffel 1997; Pisano et al. 1996). Glutamate concentrations have been shown to rise to excitotoxic levels within minutes following traumatic or ischemic injury, and there is evidence that the function of the glutamate transporters becomes impaired under these excitotoxic conditions (Faden et al. 1989). It is surprising that the glutamatergic system has only recently undergone extensive investigation with regard to its possible involvement in the pathophysiology of mood disorders, since it is the major excitatory neurotransmitter in the CNS and known to play a role in regulating the threshold for excitation of most other neurotransmitter systems. Although direct evidence for glutamatergic excitotoxicity in bipolar disorder is lacking and the precise mechanisms underlying the cell atrophy and death that occur in recurrent mood disorders are unknown, considerable data have shown that impairments of the glutamatergic system play a major role in the morphometric changes observed with severe stresses (McEwen 1999; Sapolsky 2000).

It is now clear that modification of the levels of synaptic AMPA-type glutamate receptors—in particular by receptor subunit trafficking, insertion, and internalization—is a critically important mechanism for regulating various forms of synaptic plasticity and behavior. Recent studies have identified region-specific alterations in expression levels of AMPA and NMDA glutamate receptor subunits in subjects with mood disorders (Beneyto et al. 2007). Supporting the suggestion that abnormalities in glutamate signaling may be involved in mood pathophysiology, AMPA receptors have been shown to regulate affective-like behaviors in rodents. AMPA antagonists have been demonstrated to attenuate amphetamine- and cocaine-induced hyperactivity and psychostimulant-induced sensitization and hedonic behavior (Goodwin and Jamison 2007).

Glutamatergic Receptors

The many subtypes of glutamatergic receptors in the CNS can be classified into two major subtypes: ionotropic and metabotropic receptors (see Figure 1–7).

Ionotropic glutamate receptors

The ionotropic glutamate receptor ion channels are assemblies of homo- or hetero-oligomeric subunits integrated into the neuron's membrane. Every channel is assembled of (most likely) four subunits associated into a dimer of dimers as has been observed in crystallographic studies (Ayalon and Stern-Bach 2001; Madden 2002). Every subunit consists of an extracellular amino-terminal and ligand binding domain, three transmembrane domains, a reentrant pore loop (located between the first and second transmembrane domains), and an intracellular carboxyl-terminal domain (Hollmann et al. 1994). The subunits associate through interactions between their amino-terminal domains, forming a dimer that undergoes a second dimerization mediated by interactions between the ligand binding domains and/or between transmembrane domains (Ayalon and Stern-Bach 2001; Madden 2002). Three different subgroups of glutamatergic ion channels have been identified on the basis of their pharmacological ability to bind different synthetic ligands, each of which is composed of a different set of subunits. The three subgroups are the NMDA receptors, the AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptors, and the kainate receptor. The latter two groups are often referred to together as the "non-NMDA" receptors, but they undoubtedly subserve unique functions (see Figure 1–7). In the adult mammalian brain, NMDA and AMPA glutamatergic receptors are collocated in approximately 70% of the synapses (Bekkers and Stevens 1989). By contrast, at early stages of development, synapses are more likely to contain only NMDA receptors. Radioligand binding studies have shown that NMDA and AMPA receptors are found in high density in the cerebral cortex, hippocampus, striatum, septum, and amygdala.

NMDA receptors

The NMDA receptor is activated by glutamate and requires the presence of a co-agonist, namely glycine or D-serine, to be activated, a process that likely varies in importance according to brain region (Panatier et al. 2006). However, the binding of both glutamate and glycine is still not sufficient for the NMDA receptor channel to open, since at resting membrane potential, the NMDA ion channel is blocked by Mg^{2+} ions. Only when the membrane is depolarized (e.g., by the activation of AMPA or kainate receptors on the same postsynaptic neuron) is the Mg^{2+} blockade relieved. Under these conditions, the NMDA receptor channel will open and permit the entry of both Na^{+} and Ca^{2+} (see Figure 1–7).

The NMDA receptor channel is composed of a combination of NR1, NR2A, NR2B, NR2C, NR2D, NR3A, and NR3B subunits (see Figure 1–7). The binding site for glutamate has been localized to the NR2 subunit, and the site for the co-agonist glycine has been localized to the NR1 subunit, which is required for receptor function. Two molecules of glutamate and two of glycine are thought to be necessary to activate the ion channel. Within the ion channel, two other sites have been identified—the sigma (σ) site and the phencyclidine (PCP) site. The hallucinogenic drug PCP, ketamine, and the experimental drug dizocilpine (MK-801) all bind at the latter site and are considered noncompetitive receptor antagonists that inhibit NMDA receptor channel function.

In clinical psychiatric studies, ketamine has been shown to transiently induce psychotic symptoms in schizophrenic patients and to produce antidepressant effects in some depressed patients (Krystal et al. 2002). Building on these preclinical and preliminary clinical data, recent clinical trials have investigated the clinical effects of glutamatergic agents in subjects with mood disorders. Recent clinical studies have demonstrated effective and rapid antidepressant action of glutamatergic agents, including ketamine, an NMDA receptor antagonist, and riluzole, a glutamate release inhibitor (Sanacora et al. 2007; Zarate et al. 2006a). These and other data have led to the hypothesis that alterations in neural plasticity in critical limbic and reward circuits, mediated by increasing the postsynaptic AMPA-to-NMDA throughput, may represent a convergent mechanism for antidepressant action (Zarate et al. 2006b). This line of research holds considerable promise for developing new treatments for depression and bipolar disorder. The NMDA receptor agonists glycine, D-serine, and D-cycloserine have been shown to improve cognition and decrease negative symptoms in patients with schizophrenia who are receiving antipsychotics (Coyle et al. 2002). NMDA receptors in the amygdala may also be of critical importance in the process of transforming a fixed and consolidated fear memory to a labile state (Ben Mamou et al. 2006).

NMDA receptors play a critical role in regulating synaptic plasticity (Malenka and Nicoll 1999). The best-studied forms of synaptic plasticity in the CNS are *long-term potentiation* (LTP) and *long-term depression* (LTD) of excitatory synaptic transmission. The molecular mechanisms of LTP and LTD have been extensively characterized and have been proposed to represent cellular models of learning and memory (Malenka and Nicoll 1999). Induction of LTP and LTD in the CA1 region of the hippocampus and in many regions of the brain has now clearly been demonstrated to be dependent on NMDA receptor activation. During NMDA receptor–dependent synaptic plasticity, Ca^{2+} influx through NMDA receptors can activate a wide variety of kinases and/or phosphatases that in turn modulate synaptic strength. An important development was the finding that two of the primary molecules involved—CaMKII and the NMDA subtype of glutamate receptor—form a tight complex with each other at the synapse (Lisman and McIntyre 2001). Interestingly, this binding appears to enhance both the autophosphorylation of the kinase and the ability of the entire holoenzyme, which has 12 subunits, to become hyperphosphorylated (Lisman and McIntyre 2001). This hyperphosphorylated state has been postulated to represent a "memory switch" that can lead to long-term strengthening of the synapse by multiple mechanisms. One important mechanism involves direct phosphorylation of the glutamate-activated AMPA receptors, which increases their conductance. Furthermore, CaMKII, once bound to the NMDA receptor, may organize additional anchoring sites for AMPA receptors at the synapse. Switching of synaptic NMDA receptor subunits, which bind CaMKII, for other NMDA receptor subunits having no affinity for this enzyme dramatically reduces LTP, demonstrating that glutamate and calcium signaling interactions are critical for learning and memory (Barria and Malinow 2005).

While the NMDA receptor clearly plays important roles in plasticity, abundant evidence has shown that excessive glutamatergic signaling is also involved in neuronal toxicity. With anoxia or hypoglycemia, the highly energy-dependent uptake mechanisms that keep glutamate compartmentalized in presynaptic terminals fail. Within minutes, glutamate is massively released into the synaptic space, resulting in activation of excitatory amino acid receptors. This leads to depolarization of target neurons via AMPA and kainate receptors and then to inappropriate and excessive activation of NMDA receptors. Considerable data suggest that the large excess of Ca^{2+} entering cells via the NMDA receptor channel may represent an important step in the rapid cell death that occurs

via excitotoxicity.

AMPA receptors

The AMPA receptor is stimulated by the presence of glutamate and characteristically produces a fast excitatory synaptic signal that is responsible for the initial reaction to glutamate in the synapse. In fact, as discussed above, it is generally believed that it is the activation of the AMPA receptor that results in neuronal depolarization sufficient to liberate the Mg^{2+} cation from the NMDA receptor, thereby permitting its activation. The AMPA receptor channel is composed of the combination of the GluR1, GluR2, GluR3, and GluR4 subunits and requires two molecules of glutamate to be activated (see Figure 1–7). AMPA receptors have a lower affinity for glutamate than does the NMDA receptor, thereby allowing for more rapid dissociation of glutamate and, therefore, a rapid deactivation of the AMPA receptor (for a review, see Dingledine et al. 1999).

Studies have indicated that AMPA receptor subunits are direct substrates of protein kinases and phosphatases. Phosphorylation of the receptor subunits regulates not only the intrinsic channel properties of the receptor but also the interaction of the receptor with associated proteins that modulate the membrane trafficking and synaptic targeting of the receptors (discussed in Malinow and Malenka 2002). Additionally, protein phosphorylation of other synaptic proteins has been proposed to indirectly modulate AMPA receptor function by affecting the macromolecular complexes that are important for the presence of AMPA receptors at the synaptic plasma membrane (Malinow and Malenka 2002; Nestler et al. 2001). Studies have been elucidating the cellular mechanisms by which AMPA receptor subunit insertion and trafficking occur and have revealed two major mechanisms (Malinow and Malenka 2002; Nestler et al. 2001). The first mechanism is used for GluR1-containing AMPA receptor insertion and is regulated by activity. The second mechanism is governed by constitutive receptor recycling, mainly through GluR2/3 heteromers in response to activity-dependent signals. Data suggest that AMPA receptor subunit trafficking may play an important role in neuropsychiatric disorders. Thus, Nestler and associates have shown that the ability of drugs of abuse to elevate levels of the GluR1 subunit of AMPA glutamate receptors in the VTA of the midbrain is crucial for the development of sensitization (Carlezon and Nestler 2002). They have demonstrated that even transient increases in GluR1 levels within VTA neurons can trigger complex cascades of other molecular adaptations in these neurons and, within larger neural circuits, can cause enduring changes in the responses of the brain to drugs of abuse. Chronic lithium and valproate have been shown to reduce GluR1 expression in hippocampal synaptosomes, effects that may play a role in the delayed therapeutic effects of these agents (Du et al. 2003; Szabo et al. 2002).

Recent studies have sought to test the hypothesis that "antidepressant anticonvulsants," like traditional antidepressants, can enhance surface AMPA receptors (Du et al. 2007). It was found that the predominantly antidepressant anticonvulsants lamotrigine and riluzole significantly enhanced the surface expression of GluR1 and GluR2 in a time- and dose-dependent manner in cultured hippocampal neurons. By contrast, the predominantly antimanic anticonvulsant valproate significantly reduced surface expression of GluR1 and GluR2. Concomitant with the GluR1 and GluR2 changes, the peak value of depolarized membrane potential evoked by AMPA was significantly higher in lamotrigine- and riluzole-treated neurons, supporting the surface receptor changes. In addition, lamotrigine and riluzole, as well as the traditional antidepressant imipramine, increased GluR1 phosphorylation at GluR1 (S845) in the hippocampus after chronic in vivo treatment.

Recent clinical research has demonstrated a robust and rapid antidepressant effect of ketamine; studies were therefore undertaken to test the hypothesis that ketamine brings about its rapid antidepressant effect by enhancing AMPA relative to NMDA throughput (Maeng et al. 2008). Although the AMPA antagonist NBQX was without behavioral effects alone, it blocked the antidepressant-like effects of ketamine. AMPA antagonists also blocked ketamine-induced changes in hippocampal GluR1 AMPA receptor phosphorylation. Together, these results suggest that regulating AMPA relative to NMDA throughput in critical neuronal circuits may play an important role in antidepressant action.

Kainate receptors

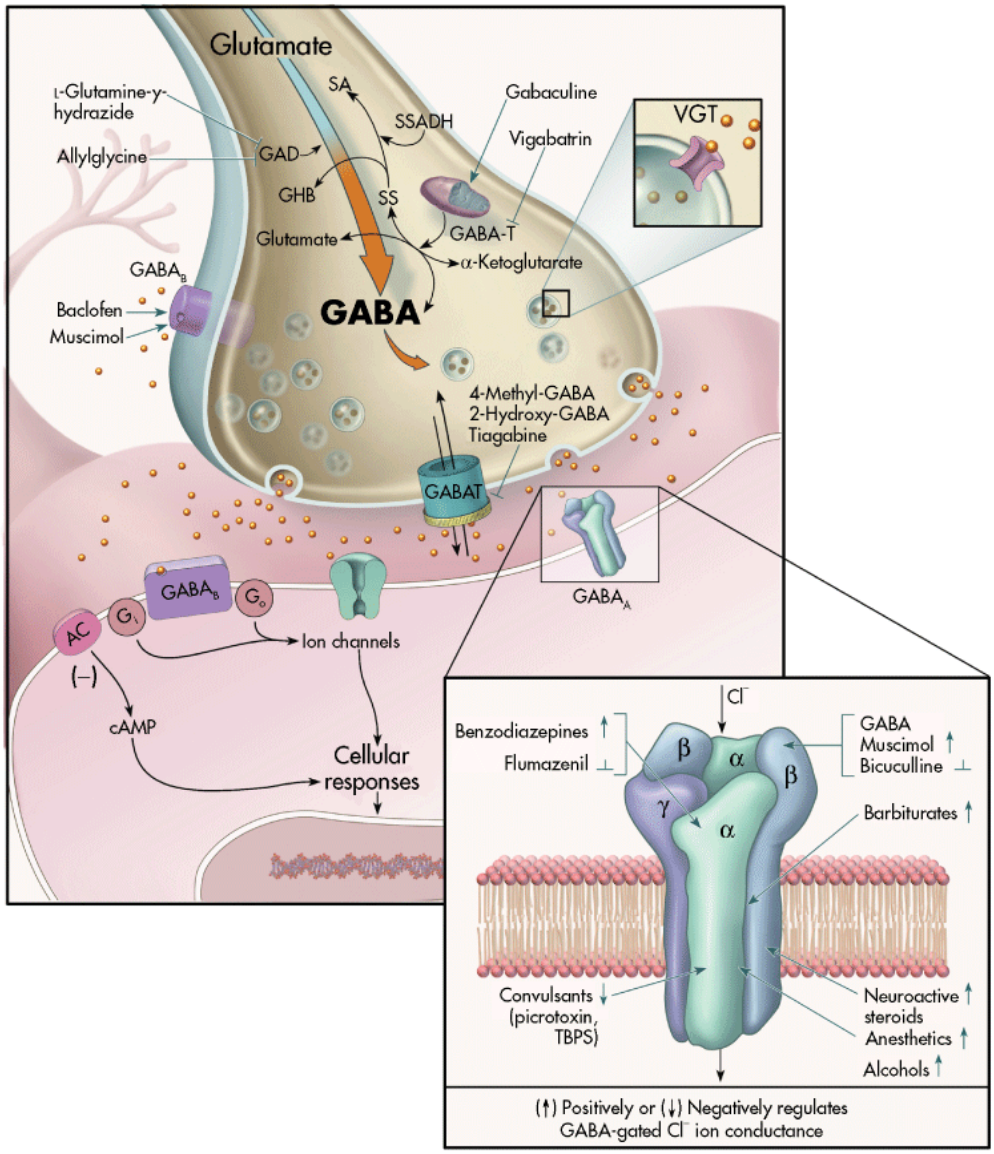
The kainate receptor has pre- and postsynaptic roles, sharing some properties with AMPA receptors. It is composed of the combination of the GluR5, GluR6, GluR7, KA1, and KA2 subunits (see Figure 1–7). The precise role of kainate receptors in the mature CNS remains to be fully elucidated, although the activity of the receptors clearly plays a role in synaptic function in many brain areas. Increasing data suggest the involvement of aberrant synaptic plasticity in the pathophysiology of bipolar disorder. Kainate receptors contribute to synaptic plasticity in different brain regions involved in mood regulation, including the prefrontal cortex, hippocampus, and amygdala. GluR6 (GRIK2) is a subtype of kainate receptor whose chromosomal loci of 6q16.3–q21 have been identified as potentially harboring genetic polymorphism(s) contributing to an increased risk of mood disorders. The role of GluR6 in modulating animal behaviors correlated with mood symptoms was investigated using GluR6 knockout and wild-type mice (Shaltiel et al. 2008). GluR6 knockout mice appeared to attain normal growth and showed no neurological abnormalities. GluR6 mice showed increased basal- or amphetamine-induced activity, were extremely aggressive, took more risks, and consumed more saccharin (a measure of hedonic drive). Notably, most of these aberrant behaviors responded to chronic lithium administration. These results suggest that abnormalities in kainate receptor throughput generated by GluR6 gene disruption may lead to the concurrent appearance of a constellation of behaviors related to manic symptoms, including persistent hyperactivity; escalated irritability, aggression, and risk taking; and hyperhedonia.

Metabotropic glutamate receptors

The metabotropic glutamate receptors (mGluRs) are G protein–coupled receptors. The eight types of receptors that currently have been cloned can be organized into three different subgroups (groups I, II, and III) based largely on the signaling transduction pathways that they activate (see Figure 1–7). These receptors have a large extracellular N-terminal consisting of two lobes forming a "venus flytrap" binding pocket involved in glutamate recognition and a cysteine-rich extracellular domain that connects with seven transmembrane domains separated by short intra- and extracellular loops (see Figure 1–7). The intracellular loop plays an important role in the coupling with and selectivity of the G protein. The cytoplasmic carboxyl-terminal domain is variable in length and is involved with G protein activation and coupling efficacy (Bruno et al. 2001; Conn and Pin 1997).

The mGluR group I includes the mGluR1 (a, b, c, d), and mGluR5 (a, b) receptors (see Figure 1–7). They preferentially interact with the $G\alpha_{q/11}$ subunit of G proteins, leading to activation of the IP_3/calcium and DAG/PKC cascades. The receptors are located on both pre- and postsynaptic neurons. Group II metabotropic receptors include mGluR2 and mGluR3, which have been best characterized as inhibiting adenylyl cyclase but, like many receptors coupled to G_i/G_o, may also regulate ion channels. Group III receptors, which include mGluR4 (a, b), mGluR6, mGluR7 (a, b), and mGluR8 (a, b), are reported to produce inhibition of adenylyl cyclase as well, but also to interact with the phosphodiesterase enzyme regulating guanosine monophosphate (cGMP) levels (Cooper et al. 2001; Squire et al. 2003). The group II and III receptors are located in the presynaptic membrane and, because of their coupling with G_i/G_o proteins, appear to negatively modulate glutamate and GABA neurotransmission output when activated (i.e., they serve as inhibitory auto- and heteroreceptors). Preclinical studies suggest that mGlu group II and III receptors are "extrasynaptic" in their localization; that is, they are located some distance from the synaptic cleft and are thus activated only under conditions of excessive (pathological?) glutamate release, when there is sufficient glutamate to diffuse out of the synapse to these receptors (Schoepp 2001). In preclinical studies, mGluR2/3 agonists have been demonstrated to exert anxiolytic, antipsychotic, and neuroprotective properties (Schoepp 2001).

Glycine



Glycine is a nonessential amino acid that also functions as a neurotransmitter in the CNS. Although the exact metabolic pathway for glycine production has yet to be fully elucidated, evidence suggests that glycine may be produced in the CNS by two distinct pathways. First, glycine is produced from serine by the enzyme serine-*trans*-hydroxymethylase in a reversible folate-dependent reaction (Cooper et al. 2001; Squire et al. 2003). Additionally, glycine may be produced from glyoxylate by the enzyme D-glycerate dehydrogenase. This amino acid is found in higher concentrations in the spinal cord than in the rest of

the CNS. Glycine acts as an inhibitory neurotransmitter predominantly in the brain stem and spinal cord (Nestler et al. 2001). As discussed earlier, a very important role that glycine also plays is to augment the NMDA-mediated frequency of NMDA receptor channel opening. This effect is strychnine-insensitive and pharmacologically suggests that the actions of glycine on NMDA receptor function are different from its effect on the spinal cord, where glycine's inhibitory effect is blocked by strychnine (Cooper et al. 2001). The allosteric modulation of NMDA receptors via a glycine-insensitive site is further underscored by receptor binding experiments yielding an anatomic distribution similar to that of NMDA receptors. Functionally, it has been postulated that glycine is able to augment the NMDA-mediated responses by speeding up the recovery process of the receptor (Cooper et al. 2001). Given the ability of glycine to alter NMDA function, glycine may be beneficial in the treatment of schizophrenia (Coyle et al. 2002).

GABAergic System

γ-Aminobutyric acid—the major inhibitory neurotransmitter system in the CNS—is one of the most abundant neurotransmitters, and GABA-containing neurons are located in virtually every area of the brain. Unlike the monoamines, GABA occurs in the brain in high concentrations in the order of micromoles per milligrams (about 1,000-fold higher than concentrations of monoamines) (Cooper et al. 2001; Nestler et al. 2001; Squire et al. 2003). GABA is produced when glucose is converted to α-ketoglutarate, which is then transaminated to glutamate by GABA α-oxoglutarate transaminase (GABA-T). Glutamic acid is decarboxylated by glutamic acid decarboxylase, which leads to the formation of GABA (Figure 1–8). Indeed, the neurotransmitter and the rate-limiting enzyme are localized together in the brain and at approximately the same concentration. Catabolism of GABA occurs via GABA-T, which is also important in the synthesis of this transmitter.

This figure depicts the various regulatory processes involved in GABAergic neurotransmission. The amino acid (and neurotransmitter) glutamate serves as the precursor for the biosynthesis of γ-aminobutyric acid (GABA). The rate-limiting enzyme for the process is glutamic acid decarboxylase (GAD), which utilizes pyridoxal phosphate as an important cofactor. Furthermore, agents such as L-glutamine-γ-hydrazide and allylglycine inhibit this enzyme and, thus, the production of GABA. Once released from the presynaptic terminal, GABA can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of GABA neuron firing activity and release occurs through somatodendritic (not shown) and nerve-terminal $GABA_B$ receptors, respectively. Baclofen is a $GABA_B$ receptor agonist. The binding of GABA to ionotropic $GABA_A$ receptors and metabotropic $GABA_B$ receptors mediates the effects of this receptor. The $GABA_B$ receptors are thought to mediate their actions by being coupled to Ca^{2+} or K^+ channels via second-messenger systems. Many agents are able to modulate $GABA_A$ receptor function. Benzodiazepines, such as diazepam, increase Cl^- permeability, and

there are numerous available antagonists directed against this site. There is also a distinctive barbiturate binding site on $GABA_A$ receptors, and many psychotropic agents are capable of influencing the function of this receptor (see blown-up diagram). GABA is taken back into presynaptic nerve endings by a high-affinity GABA uptake transporter (GABAT) similar to that of the monoamines. Once inside the neuron, GABA can be broken down by GABA transaminase (GABA-T), which is localized in the mitochondria; GABA that is not degraded is sequestered and stored into secretory vesicles by vesicle GABA transporters (VGTs), which differ from VMATs in their bioenergetic dependence. The metabolic pathway that produces GABA, mostly from glucose, is referred to as the *GABA shunt.* The conversion of α-ketoglutarate into glutamate by the action of GABA-T and GAD catalyzes the decarboxylation of glutamic acid to produce GABA. GABA can undergo numerous transformations, of which the simplest is the reduction of succinic semialdehyde (SS) to γ-hydroxybutyrate (GHB). On the other hand, when SS is oxidized by succinic semialdehyde dehydrogenase (SSADH), the production of succinic acid (SA) occurs. GHB has received attention because it regulates narcoleptic episodes and may produce amnestic effects. The mood stabilizer and antiepileptic drug valproic acid is reported to inhibit SSADH and GABA-T. TBPS = *t*-butylbicyclophosphorothionate.

The function of this dual-role enzyme becomes apparent when placed in the context of its role in the metabolic process. GABA-T converts GABA to succinic acid, and subsequent removal of the amino group yields α-ketoglutarate. Thus, α-ketoglutarate is able to be used by GABA-T in GABA biosynthesis as mentioned above (Cooper et al. 2001). This process, called the *GABA shunt,* maintains a steady GABA supply in the brain. As with the monoamines, the major mechanism by which the effects of GABA are terminated in the synaptic cleft is by reuptake through GABA transporters. The GABA transporters have a high affinity for GABA and mediate their reuptake via a Na^+ and Cl^- gradient (Squire et al. 2003).

Detailed studies from the Rajkowska laboratory (Grazyna Rajkowska, The University of Mississippi Medical Center, Jackson, MS) have measured the density and size of calbindin-immunoreactive neurons (presumed to be GABAergic) in layers II and III of the dorsolateral prefrontal cortex, revealing a 43% reduction in the density of these neurons in patients with major depressive disorder compared with controls (discussed in Goodwin and Jamison 2007). Of particular note, in the rostral orbitofrontal cortex, there was a trend toward a negative correlation between the duration of depression and the size of neuronal cell bodies, suggesting changes associated with disease progression. Valproate has also been shown to have neurogenic effects in at least one study. In cultured embryonic rat cortical cells and striatal primordial stem cells, valproate markedly increased the number and percentage of primarily GABAergic neurons and promoted neurite outgrowth (Laeng et al. 2004).

GABA Receptors

There are two major types of well-characterized GABA receptors, $GABA_A$ and $GABA_B$, and most neurons in the CNS possess at least one of these types. The $GABA_A$ receptor is the more prevalent of the two in the mammalian CNS and as a result has been extensively studied and characterized. $GABA_A$ contains an integral transmembrane chloride channel, which is opened upon receptor activation, generally resulting in hyperpolarization of the neuron (i.e., suppressing excitability). The GABA receptor is a heteropentameric glycoprotein of approximately 275 kDa composed of a combination of multiple polypeptide subunits. $GABA_A$ displays enormous heterogeneity, being composed of a combination of five classes of polypeptide subunits (α, β, γ, δ, ε), of which there are at least 18 total subtypes. The various receptors display variation in functional pharmacology, hinting at the multiple finely tuned roles that inhibitory neurotransmission plays in brain function.

It is now well established that benzodiazepines (BZDs) function by binding to a potentiator site on the $GABA_A$ receptor, increasing the amplitude and duration of inhibitory postsynaptic currents in response to GABA binding. Coexpression of additional γ subunits is believed to be necessary for the potentiation of GABA-mediated responses by BZDs. In addition to BZDs, barbiturates and ethanol are also believed to exert many of their effects by potentiating the opening of the $GABA_A$ receptor chloride channel (see Figure 1–8). As noted earlier, $GABA_A$ receptors have a widespread distribution in the brain, and the majority of these receptors in the brain are targets of the currently available BZDs. For this reason, there has been considerable interest in determining if the desirable and undesirable effects of BZDs can be differentiated on the basis of the presence of different subunit composition. Much of the work has used gene knockout technology; thus, mutation of the BZD-binding site of the α_1 subunit in mice blocks the sedative, anticonvulsive, and amnesic, but not the anxiolytic, effects of diazepam (see Gould et al. 2003; Mohler et al. 2002). In contrast, the α_2 subunit (expressed highly in the cortex and hippocampus) is necessary for diazepam anxiolysis and myorelaxation. Thus, there is now optimism that an α_2-selective ligand will soon provide effective acute treatment of anxiety disorders without the unfavorable side-effect profile of current BZDs. A compound with this preferential affinity has already been demonstrated to exert fewer sedative/depressant effects than diazepam in rat behavioral studies (see Gould et al. 2003; Mohler et al. 2002).

The phosphorylation of $GABA_A$ receptors is another mechanism by which this receptor complex can be regulated in function and expression. In this context, it is noteworthy that studies have reported that knockout mice deficient in PKC ε isoforms show reduced anxiety and alcohol consumption and an enhanced response to the effects of BZDs (discussed in Gould et al. 2003). Furthermore, different $GABA_A$ receptor subunit partnerships, such as α_1/δ, mediate tonic inhibitory currents in the hippocampus and are highly sensitive to low concentrations of ethanol (Glykys et al. 2007).

The $GABA_B$ receptors are coupled to G_i and G_o and thereby regulate adenylyl cyclase activity (generally inhibit), K^+ channels (open), and Ca^{2+} channels (close). $GABA_B$ receptors can function as an autoreceptor but are also found abundantly postsynaptically on non-GABAergic neurons. Of interest, there is mounting evidence that receptor dimerization may be required for the activation of $GABA_B$ and possibly other G protein–coupled receptors; although receptor dimerization has long been known to occur for growth factor and JAK (Janus tyrosine kinase)/STAT (signal transducers and activators of transcription) receptors (discussed later in this chapter), this was not expected for GPCRs. However, studies have reported that coexpression of two $GABA_B$ receptor subunits—subunit 1 ($GABA_BR1$) and subunit 2 ($GABA_BR2$)—is necessary for the formation of a functional $GABA_B$ receptor (Bouvier 2001). Some data suggest that $GABA_BR2$ may be necessary for proper protein folding of $GABA_BR1$ (acting as a molecular chaperone) in the endoplasmic reticulum, but this remains to be definitively established. Support for the physiological relevance of this dimerization comes from studies showing that the $GABA_B$ R1 and R2 subunits can be co-immunoprecipitated in rat cortical membrane preparations (Kaupmann et al. 1997); thus, the dimerization is not simply an in vitro phenomenon.

PURINERGIC NEUROTRANSMISSION: FOCUS ON ADENOSINE

It has been known for quite some time that ATP is capable of exerting profound effects on the nervous system (Drury and Szent-Gyšrgyi 1929). However, adenosine and adenosine nucleotides have gained acceptance as neuroactive substances in the CNS only relatively recently (Cooper et al. 2001). Adenosine is released from neurons and glia, but many of the neurotransmitter criteria outlined in the beginning of this chapter are not met. Nonetheless, adenosine is able to activate many cellular functions that are able to produce changes in neuronal and behavioral states. For example, adenosine is able to stimulate cAMP in vitro in brain slices, and caffeine (which in addition to being a phosphodiesterase inhibitor is a well-known adenosine receptor antagonist) is able to block this response.

Four adenosine receptors have been cloned (A_1, A_{2A}, A_{2B}, and A_3), each of which exhibits unique tissue distribution, ligand binding affinity (nanomolar range), and signal transduction mechanisms (Cooper et al. 2001). Currently available data suggest that the high-affinity adenosine receptors (A_1 and A_{2A}) may be activated under normal physiological conditions, whereas in pathological states such as hypoxia and inflammation (in which high adenosine concentrations [micromolar range] are present), low-affinity A_{2B} and A_3 receptors are also activated. A_{2B} receptors are expressed in low levels in the brain but are ubiquitous in the rest of the body, whereas A_{2A} receptors are found in high concentrations in areas of the brain that receive dopaminergic projections (i.e., striatum, nucleus accumbens, and olfactory tubercle) (Nestler et al. 2001). Given this receptor's distribution and the inverse relationship between DA and adenosine, it has been postulated that A_{2A} antagonists may have some utility in the treatment of Parkinson's disease (Nestler et al. 2001).

The mood stabilizer and antiepileptic drug carbamazepine acts as an antagonist of the A1 subtype and also decreases protein levels of the receptor (for a review, see Gould et al. 2002).

Adenosine is widely regarded as important in the homeostasis of blood flow and metabolic demands in peripheral tissue physiology. Adenosine is also able to alter the function (both pre- and postsynaptically) of numerous neurotransmitters and their receptors, including NMDA, metabotropic glutamate receptors, ionotropic nicotinic receptors, NE, 5-HT, DA, GABA, and various peptidergic receptors. Recent evidence implicates adenosine as a fatigue factor in the decrease of cholinergic activity-arousal via presynaptic inhibition of glutamate release (Brambilla et al. 2005). In addition, P2X (ligand-gated ion channels) and P2Y (G protein–coupled receptors) are purine receptors that can be activated by ATP. It has been demonstrated that ATP is released from astrocytes (through an unknown mechanism) and that the release is accompanied by glutamate release (Ca^{2+}-dependent) (Innocenti et al. 2000). However, more data suggest that it may be adenosine (that is derived from ATP) that serves as the true ligand for these purinergic receptors (Fields and Stevens-Graham 2002). The ATP/adenosine is then able to activate purine receptors (P_{2Y} receptors) on neighboring astrocytes, and this stimulates Ca^{2+} influx and subsequent release of glutamate and ATP to then impact other astrocytes and neurons. This may be a critical component in the communication process between glial cells, as well as representing a signaling molecule from glia to neurons (Fields and Stevens-Graham 2002).

PEPTIDERGIC NEUROTRANSMISSION

Neuropeptides have garnered increasing attention as critical modulators of CNS function. In general, peptide transmitters are released from neurons when they are stimulated at higher frequencies from those required to facilitate release of traditional neurotransmitters, but they can also be colocalized and coreleased together with other neurotransmitters (Cooper et al. 2001; Nestler et al. 2001). Modulation of the firing rate pattern of neurons and subsequent release of neurotransmitters and peptides in a circumscribed fashion are likely important in the basal functioning of the brain as well as response to specific stimuli. For instance, cannabinoids, an example of a neuropeptide neurotransmitter, do not alter the firing rates of hippocampal neurons but instead change the temporal coordination of those neurons, an effect that correlates with memory deficits in individuals (Soltesz and Staley 2006). Virtually every known mammalian bioactive peptide is synthesized first as a precursor protein in which product peptides are flanked by cleavage sites. Neuropeptides are generally found in large dense-core vesicles, whereas other neurotransmitters, such as the monoamines, are packaged in small synaptic vesicles (approximately 50 nm) and are usually half the size of their peptidergic counterparts (Kandel et al. 2000; Squire et al. 2003).

Space limitations preclude an extensive discussion of the diverse array of neuropeptides known to exist in the mammalian brain. Table 1–2 highlights some of the major neuropeptides that may be of particular psychiatric relevance. In the remainder of this section, the basic aspects of peptidergic transmission are highlighted vis-à-vis an overview of opioidergic neurotransmission.

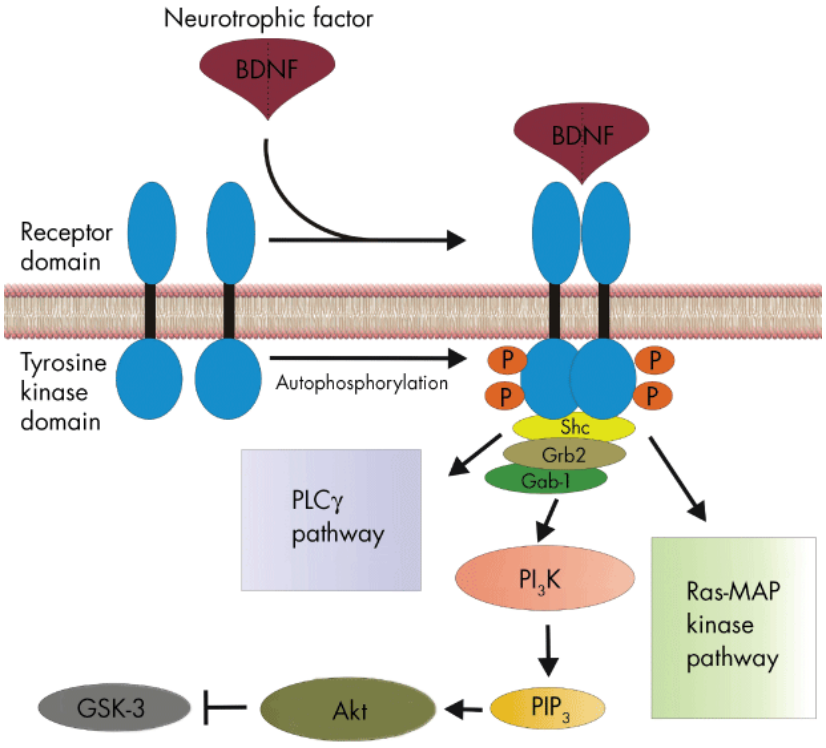
TABLE 1–2. Selected peptides and their presumed relevance to psychiatric disorders and treatment

Group	Potential clinical reference
Opioid and related peptides	
Endorphin	All of these peptides may be involved in opiate dependence/drug abuse; possible antidepressant activity; chronic pain
Enkephalin	
Dynorphin	
Nociceptin	
Gut-derived peptides	
VIP	Sexual behavior
CCK	Anxiety/panic
Gastrin	
Secretin	Autism?
Somatostatin	Mood disorders and treatment
Tachykinin peptides	
Substance P	NK_1 receptor antagonists may alleviate depression/anxiety
Substance K	Regulated by antipsychotics
Neuromedin N	Regulated by lithium
Pituitary peptides	
Oxytocin	Affiliative behavior
Vasopressin	Potential novel anxiolytics?
ACTH	Dysregulated in mood disorders
MSH	
Hypothalamic releasing factors	
CRF	Strongly implicated in depressive and anxiety symptoms; potential target for novel treatments
TRF	Potential antidepressant effects
GHRF	
LHRF	
Others	
Calcitonin gene–related peptide	Regulated by ECT and lithium
Angiotensin	Mood disorders, bipolar disorder
Neurotensin	Regulated by antipsychotics and stimulants
Leptin	Satiety signal; involved in diagnosis and in treatment-induced appetite/weight changes?
CART	Drug addiction, eating disorders
Galanin	Potentially relevant for Alzheimer's diagnosis and other cognitive disorders
Neuropeptide Y	Potential endogenous anxiolytic; regulated by antidepressants/lithium; reduced by early maternal separation

Group	Potential clinical reference
Orexin/hypocretin	Narcolepsy; sleep abnormalities in other disorders?

Note. This table summarizes selected peptides and their presumed relevance for psychiatric disorders and their treatment; it is not meant to be an exhaustive listing of findings. It should also be noted that in some cases—for example, CRF (mood/anxiety), NPY and neurotensin (regulation by medications), oxytocin (affiliative behavior), and orexin (narcolepsy)—the data are quite convincing. In many of the other examples noted, the evidence must be considered preliminary but is, in our opinion, quite noteworthy and warrants further investigation. ACTH = adrenocorticotropic hormone; CART = cocaine- and amphetamine-related transcript; CCK = cholecystokinin; CRF = corticotropin-releasing factor; ECT = electroconvulsive therapy; GHRF = growth hormone–releasing factor; LHRF = luteinizing hormone–releasing factor; MSH = melanocyte-stimulating hormone; NPY = neuropeptide Y; TRF = thyrotropin-releasing factor; VIP = vasoactive intestinal peptide.

Opioids **are a family of peptides that occur endogenously in the brain (endorphins), as botanicals, or as drugs. Pro-opiomelanocortin (POMC), proenkephalin-derived peptides, and prodynorphin-derived peptides yield opioid peptides upon cleavage. Three opioid peptide families currently exist: enkephalins, endorphins, and dynorphins. There are also three types of opioid receptors—namely, μ, δ, and κ—each of which is further subclassified. POMC gene expression occurs in various areas of the brain as well as other tissues. POMC has tissue- and cell-specific regulatory factors at every step from gene transcription to its posttranslational processing. Opioid peptides are stored in large dense-core vesicles and are coreleased from neurons that usually contain a classical neurotransmitter agent (e.g., glutamate and norepinephrine). Opioids activate a variety of signal transduction processes, and different mechanisms in their regulation are in place for different cell types. The opioid receptors are G protein–coupled receptors and exert their cellular effects by inhibiting adenylyl cyclase and regulating K^+ and Ca^{2+} channels, via activation of G_i/G_o. Recently opiorphin, an endogenously derived enkephalin that inactivates zinc ectopeptidase, has been described as equal to morphine in the suppression of pain (Wisner et al. 2006). Although opiates are widely associated with and used therapeutically in pain modulation, recent evidence indicates that dynorphin can actually activate bradykinin receptors and contribute to neuropathic pain (Altier and Zamponi 2006). The continued study of the opioid system and the second-messenger changes brought about by the chronic administration of opioids has greatly facilitated our understanding of the molecular and cellular effects of drugs of abuse and the potential to develop novel therapeutics (Nestler et al. 2001).**



NEUROTROPHINS

Neurotrophins are a family of regulatory factors that mediate the differentiation and survival of neurons, as well as the modulation of synaptic transmission and synaptic plasticity (Patapoutian and Reichardt 2001; Poo 2001). The neurotrophin family now includes, among others, nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT_3), neurotrophin-4/5 ($NT_{4/5}$), and neurotrophin-6 (NT_6) (Patapoutian and Reichardt 2001). These various proteins are closely related in terms of sequence homology and receptor specificity. They bind to and activate specific tyrosine receptor kinases belonging to the Trk family of receptors, including TrkA, TrkB, and TrkC, and a pan-neurotrophin receptor p75 (Patapoutian and Reichardt 2001; Poo 2001). Additionally, there are two isoforms of TrkB receptors: the full-length TrkB and the truncated form of TrkB, which does not contain the intracellular tyrosine kinase domain (Fryer et al. 1996). The truncated form of TrkB can thus function as a dominant-negative inhibitor for the TrkB receptor tyrosine kinase, thereby providing another mechanism to regulate BDNF signaling in the CNS (Eide and Virshup 2001; Gonzalez et al. 1999).

Neurotrophins can be secreted constitutively or transiently, and often in an activity-dependent manner. Observations support a model in which neurotrophins are generally secreted from the dendrite and act retrogradely at presynaptic terminals, where they act to induce long-lasting modifications (Poo 2001). Within the neurotrophin family, BDNF is a potent physiological survival factor that has also been implicated in a variety of pathophysiological conditions, such as Parkinson's disease, Alzheimer's disease, diabetic peripheral neuropathy, and psychiatric disorders (Malberg et al. 2000; Nagatsu et al. 2000; Pierce and Bari 2001; Salehi et al. 1998). In particular, a genetic variant of BDNF (Val66Met) has been associated with risk for development of mood disorders in humans, as well as with mood- and anxiety-related behaviors and response to antidepressant medications in animal models (Z. Y. Chen et al. 2006; Neves-Pereira et al. 2002; Sklar et al. 2002). Recent data also support a role for this polymorphism in human brain development and function (Frodl et al. 2007; Kleim et al. 2006). The cellular actions of BDNF are mediated through two types of receptors: a high-affinity tyrosine receptor kinase (TrkB) and a low-affinity pan-neurotrophin receptor (p75) (see Figure 1–1 for details). TrkB is preferentially activated by BDNF and NT4/5 and appears to mediate most of the cellular responses to these neurotrophins (Du et al. 2003; Poo 2001).

Binding of BDNF initiates TrkB dimerization and transphosphorylation of tyrosine residues in its cytoplasmic domain (Patapoutian and Reichardt 2001), a process that involves cAMP activation (Ji et al. 2005). Binding of cytoplasmic src homology 2 (SH2) domain–containing scaffolding proteins—including Shc and Grb-2, which recognize specific phosphotyrosine residues on the receptor—can thus result in the recruitment of a variety of effector molecules. This recruitment of effector molecules generally occurs via interaction of proteins with modular binding domains SH2 and SH3 (named after homology to the src oncogenes—src homology domains). The ability of multiple effectors to interact with phosphotyrosines is undoubtedly one of the keys to the pleiotropic effects that neurotrophins can exert. The physiological effects of neurotrophins are mediated by varying degrees of activation of three major signaling pathways—the Ras/MAP kinase pathway, the phosphoinositide-3 kinase (PI_3K) pathway, and the phospholipase C–γ1 (PLC-γ1) pathway (Figure 1–9). Among these pathways, the effects of the PI_3K pathway and the MAP kinase pathway have traditionally been linked to the cell survival effects of neurotrophins (Patapoutian and Reichardt 2001) (see Figure 1–9). A series of studies by Duman (2002) have shown that BDNF and TrkB are upregulated by antidepressant treatment. The "neurotrophin hypothesis of depression" has enjoyed heuristic value in reconceptualizing mood disorders as arising from abnormalities in neural plasticity cascades. The demonstration that decreases in hippocampal BDNF levels are correlated with stress-induced depressive behaviors and that antidepressant treatment enhances BDNF expression has generated considerable interest. It is now accepted that the main function of BDNF in the adult brain is regulating synaptic plasticity rather than mediating neuronal survival. Exciting results show that BDNF is first synthesized as a precursor proBDNF, which is then proteolytically cleaved to mature BDNF (mBDNF). ProBDNF and mBDNF facilitate LTD and LTP, respectively, suggesting opposing cellular functions. Finally, BDNF plays different and perhaps opposing roles in the brain stress versus reward system (discussed in Martinowich et al. 2007).

Cell survival is dependent on neurotrophic factors, such as brain-derived neurotrophic factor (BDNF) and nerve growth factor, and the expression of these factors can be induced by synaptic activity. Phosphorylation of tyrosine receptor kinase (Trk) receptors activates a critical signaling pathway, the Ras/MAP kinase pathway (see Figure 1–15). Phosphorylated Trk receptors also recruit the phosphoinositide-3 kinase (PI_3K) pathway through at least two distinct pathways, the relative importance of which differs between neuronal subpopulations. In many neurons, Ras-dependent activation of PI_3K is the most important pathway through which neurotrophins promote cell survival (not shown; see text). In some cells, as shown in the figure, PI_3K can also be directly activated through adaptor proteins (Shc, Grb-2, and Gab-1). PI_3K directly regulates certain cytoplasmic apoptotic pathways. Akt phosphorylates the pro-apoptotic Bcl-2 family member BAD (Bcl-xl/Bcl-2–associated death promoter), thereby inhibiting BAD's pro-apoptotic functions (Datta et al. 1997). Akt may also promote survival in an indirect fashion by regulating another major signaling enzyme: glycogen synthase kinase–3 (GSK-3) (Woodgett 2001). Interestingly, lithium is an inhibitor of GSK-3. Phosphorylated Trk receptors also recruit phospholipase C–γ1 (PLC-γ1). The Trk kinase then phosphorylates and activates PLC-γ1, which acts to hydrolyze phosphatidylinositides to generate diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP_3). Antidepressant medication and mood stabilizers increase levels of BDNF and other neurotrophic factors, suggesting a therapeutic relevance.

Retrograde Transportation of Neurotrophin Receptors as Signal to the Cell Body

Unlike most other internalized receptors, which are usually degraded after internalization, neurotrophin–Trk complexes in endocytotic vesicles function as signal transducers and provide a mechanism for long-range signaling in the neuronal cytoplasm. Several studies have provided support for the retrograde transportation model of neurotrophin–Trk complexes; these studies indicate that endocytotic vesicles containing neurotrophin–Trk complexes may be functionally active and should be viewed as activated signaling complexes that spread the cytosolic signaling of neurotrophin–Trk complexes to distant parts of the neuron via active transport mechanisms. Intriguingly, as has been shown with another tyrosine kinase (ErbB4 receptor tyrosine kinase), other hitherto unappreciated mechanisms, such as cleavage of receptor fragments, may also be operative in trafficking signals from extracellular receptors to intracellular and nuclear targets (Ni et al. 2001). Whether such novel signaling mechanisms are also utilized by neurotrophin receptors will undoubtedly be the focus of considerable future research.

Regulation of Neurotrophin Signaling by Neuronal Activity

The neurotrophic functions of neurotrophins depend in large part on a cytoplasmic signal-transduction cascade, whose efficacy may be influenced by the presence of electrical activity in the neuron. Seizure activity, as well as nonseizure activity of a frequency or intensity capable of inducing LTP, has been shown to elevate BDNF mRNA levels and to facilitate the release of BDNF from hippocampal and cortical neurons (Poo 2001). Although BDNF was originally considered to be transported only retrogradely, evidence indicates that BDNF can also act anterogradely to modulate synaptic plasticity (Poo 2001). High-frequency neuronal activity and synaptic transmission have also been shown to elevate the number of TrkB receptors on the surface of cultured hippocampal neurons through activation of the CaMKII pathway and may therefore facilitate the synaptic action of BDNF (Du et al. 2000). Thus, electrically active nerve terminals may be more susceptible to synaptic potentiation by secreted neurotrophins than are inactive terminals. Neuronal or synaptic activity is also known to promote the effects of neurotrophins on the survival of cultured retinal ganglion cells; here, neuronal or synaptic activity elevates cAMP levels to enhance the responsiveness of the neuron to neurotrophins, apparently by recruiting extra TrkB receptors to the plasma membrane (Meyer-Franke et al. 1998). Moreover, the internalization of BDNF receptor TrkB is also upregulated by activity as a retrograde signal to the cell body in cultured hippocampal neurons (this regulation is discussed in some detail in Du et al. 2003). The activity-dependent regulation of BDNF signaling on BDNF synthesis and release, TrkB insertion onto neuronal surfaces, and activated TrkB tyrosine kinase internalization are crucial for its influence on synaptic plasticity and neuronal survival.

CYTOKINES AND JAK/STAT–COUPLED RECEPTORS

There is mounting evidence that many psychiatric disorders may be associated with altered immune function. Even more convincing is the evidence that numerous medical disorders and treatments that regulate immune function are associated with psychiatric symptomatology (Evans et al. 2001). Thus, the mechanism by which the immune system is able to mediate its effects through specified signaling pathways in the CNS will undoubtedly be of increasing importance in our understanding of these complex disorders.

Numerous cytokines and growth factors are able to activate the JAK/STAT pathway; here we focus on interferons as a prototype. *Interferons* are cytokines

that subserve important antiviral, antigrowth, and immunomodulatory activities (Larner and Keightley 2000). The interferon/cytokine receptor family is a group of receptors that, on binding to an extracellular site, produce dimerization or higher-order clustering. Unlike the tyrosine kinase type receptors (Trk), these receptors associate intrinsically in a noncovalent constitutive manner with proteins of the JAK (Janus tyrosine kinase) family to mediate their effects. Signal transducers and activators of transcription (STATs), which are SH2 domain–containing transcription factors, are required for the actions of many other cytokines and growth factors.

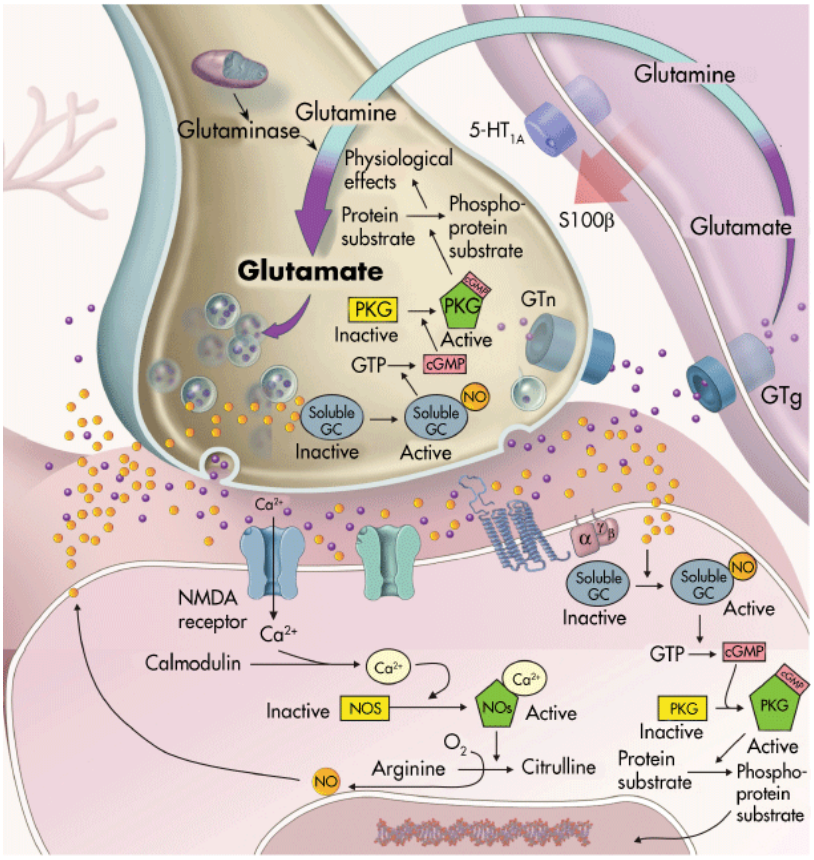
There are two types of receptors for which interferons, on binding to the extracellular part of the receptor, are able to rapidly induce corresponding genes: interferon-α/β (IFN-α/β), or type I receptors; and IFN-γ, or type II receptors. The interferon-stimulated gene factors, which are more commonly known as STATs, bind to enhancers in the promoter regions of type I and type II receptor genes to mediate transcription (Larner and Keightley 2000). It should be mentioned that in addition to interferon, interleukin-6 and prolactin are other cytokines whose effects have been documented to be mediated by STATs. STATs are modified through tyrosine kinases and are necessary for activation of early response genes on interferon binding to the receptor. Thus, the Janus tyrosine kinases (JAK1–3 and TYK2) are important in the regulation of interferon-mediated cellular effects.

Evidence suggests that IFN-α/β cluster in receptor complexes, and upon ligand binding, these proteins are able to mediate some of the receptor–effector responses of interferons. Type I interferon receptors consist of two subunits (IFNAR1 and IFNAR2), of which the IFNAR2 subunit has three isoforms (IFNAR2a, IFNAR2b, and IFNAR2c). Upon binding of interferon to IFN-α, the IFNAR2c subunit is necessary for the activation of the JAK/STAT pathway. Initially, interferons bind to two sites—IFNAR1 and IFNAR2—which heterodimerize, and then the activation of TYK2 and JAK ensues to phosphorylate the receptor (Larner and Keightley 2000). Other phosphatases and kinases are also able to interact with type I interferon receptors to produce a cascade of intercellular effects.

NUCLEAR HORMONES: FOCUS ON STEROIDS

In contrast to the other neuroactive compounds we have discussed thus far, many hormones (including cortisol, gonadal steroids, and thyroid hormones) are able to rapidly penetrate into the lipid bilayer membrane because of their lipophilic composition (Kandel et al. 2000). Retinoic acid (vitamin A) has recently been shown to be involved in sleep, as well as learning and memory formation (Drager 2006). Nuclear receptors are transcription factors that regulate the expression of target genes in response to steroid hormones and other ligands. Approximately 50 nuclear receptors are known to exist, and their structure is defined by a number of signature functional domains. Generally, nuclear receptors comprise an amino-terminal activation function, the DNA-binding domain, a hinge region, and a carboxy-terminal ligand-binding domain containing a second activation function (Kandel et al. 2000). Upon activation by a hormone, the steroid receptor–ligand complex translocates to the nucleus, where it binds to specific DNA sequences referred to as *hormone responsive elements* (HREs), which subsequently regulate gene transcription (Mangelsdorf et al. 1995; Truss and Beato 1993) (see Figure 1–1). It is now known that nuclear receptors are markedly regulated by additional "accessory proteins." *Nuclear receptor coregulators* are cellular factors that complement nuclear receptors' function as mediators of the cellular response to endocrine signals. They are generally divisible into coregulators that promote transcriptional activation when recruited (coactivators) and those that attenuate promoter activity (corepressors).

In addition to the traditional view of steroid hormone action, it is now clear, however, that steroid hormones also have so-called nongenomic effects that include changes in neurotransmitter receptors, other membrane receptors, and second-messenger systems. These effects are less well characterized, but evidence for their existence includes modulation of neural activity in brain areas where there are few, if any, gonadal steroid receptors; there is also evidence showing that estrogen directly and rapidly inhibits calcium channels in neurons (McEwen 1999; Mermelstein et al. 1996). A growing body of data is also demonstrating bidirectional cross-talk between nuclear receptors and GPCRs. Thus, for example, gonadal steroids have long been known to modulate the activity of monoaminergic neurons and receptors. More recently, it has been shown that β-adrenergic and dopamine D_1 receptors are capable of transactivating glucocorticoid and progesterone receptors, respectively. *Neuroactive steroid* is the term used for a steroid that is able not only to bind to its respective intracellular receptor and become rapidly translocated to the nucleus but also to alter neuronal excitability via interactions with certain neurotransmitter receptors (Rupprecht 2003) (see Figure 1–1). Many of the above-mentioned neuroactive steroids are capable of altering neuronal excitability by interacting with $GABA_A$ receptors. Studies using chimeras of $GABA_A$/glycine receptors suggest an allosteric action of neuroactive steroids at the *N*-terminal side of the middle of the second transmembrane domain of the GABA receptor β_1 and/or α_2 subunits (Rick et al. 1998). However, no direct binding of the steroid to the receptor has been demonstrated. In addition to $GABA_A$ receptors, other members of the ligand-gated ion channel family (including 5-HT_3, glycine, nicotinic, ACh, and glutamate receptors) have been postulated to represent targets for neuroactive steroids (Rupprecht 2003).



In view of the $GABA_A$-enhancing potential of 3α-reduced neuroactive steroids, these steroids have been suggested to possess sleep-modulating or -promoting (Mendels and Chernik 1973), anticonvulsant (Frye and Scalise 2000), anxiolytic (Crawley et al. 1986), and neuroprotective (Rupprecht 2003) properties. Finally, it has been postulated that neuroactive steroids may also contribute to psychiatric symptoms sometimes observed during pregnancy and in the postpartum period (Pearson Murphy et al. 2001).

UNCONVENTIONAL TRANSMITTERS: FOCUS ON GASES

Many of the unconventional transmitters do not fit the well-accepted neurotransmitter criteria mentioned at the beginning of this chapter. A handful of unconventional transmitters have been characterized and may ultimately prove to have relevance for neuropsychiatric disorders; here, we limit ourselves to a discussion of the gases nitric oxide (NO) and carbon monoxide (CO), which have been demonstrated to exhibit neurotransmitter-like properties in the brain (Dawson and Snyder 1994). The gases, as a result of being small and uncharged, are able to permeate the lipid bilayer and enter the neuron and directly affect certain second-messenger generating systems directly.

Synthesis of NO is derived from arginine via an enzymatic reaction involving NO synthase, flavin adenine dinucleotide, and flavin mononucleotide enzyme (Cooper et al. 2001). Currently, there are three different variations of NO synthase, which arise from different genes that share approximately 50% sequence homology. The neuronal NO synthase is activated by Ca^{2+} and calmodulin and is also regulated by phosphorylation, which decreases its function. NO is released from both neurons and glia and can activate the enzyme guanylate cyclase to augment cGMP concentrations, thereby regulating a variety of neurotransmitter systems (Cooper et al. 2001) (Figure 1–10). These effects likely occur via the activation of protein kinase G (termed *G* because it is activated by cGMP), but this remains to be definitely established. Notably, endocannabinoids, a class of fatty acid derivatives that bind to cannabinoid receptors, exert prominent effects on NO signaling (Alger 2005).

This figure depicts the various regulatory processes involved in nitric oxide (NO) signaling. Reactive oxygen species, in particular several gases, represent yet another means by which the brain is able to transmit messages. NO is formed via NO synthase (NOS), an enzyme that is generally activated by Ca^{2+}-calmodulin. As such, Ca^{2+} entry into cells via NMDA (*N*-methyl-D-aspartate) receptor activation is an important means of activating NOS. NOS yields NO by converting arginine to citrulline using O_2. NO then converts GTP to cGMP, which then is able to target soluble guanylyl cyclases (GCs) (enzymes that are similar to adenylyl cyclases but are activated by cGMP rather than cAMP). cGMP then activates the protein kinase (PKG) and, through the conversion of ATP to ADP, phosphorylates many proteins to bring about the physiological effects of NO. Once produced, NO is then able to diffuse out of the neuron and act on other cells as a signaling molecule. Interestingly, NO is able to also diffuse back to the presynaptic terminal, acting as a *retrograde transmitter,* and is thought to be important in reshaping synaptic connections (i.e., it has been linked to long-term potentiation). NO is labeled in yellow; glutamate is labeled in purple. GTg = glial transporter for glutamate; GTn = neuronal transporter for glutamate; 5-HT_{1A} = serotonin$_{1A}$ receptor; S100β = calcium-binding protein expressed primarily by astrocytes.

CO appears to be formed in neurons exclusively by heme oxygenase–2 (HO-2), which cleaves the heme ring, releasing biliverdin, expelling iron from the heme ring, and releasing a one-carbon fragment as CO. HO-2 activity occurs in neuronal populations in numerous parts of the brain and is dynamically regulated by neuronal impulses through a kinase cascade in which PKC activates casein kinase–2, which in turn phosphorylates and activates HO-2. HO-2 activity generates low micromolar concentrations of CO in the brain.

Similar to NO, CO augments cGMP levels to produce its effects in the brain. Additionally, protein carboxyl methylation and phospholipid methylation involve *S*-adenosylmethionine acting as the methyl donor. Protein carboxyl methylation and phospholipid methylation are able to impact certain aspects of brain function (i.e., calmodulin-linked enzymes), and indeed both NO and CO have been implicated in long-term neural alterations such as learning and memory. Thus, it has been presumed that these gases could influence events in the nucleus, such as transcription. When released from postsynaptic neurons, these gases have feedback potential that impacts neurotransmitter release, states of neuronal activity, and notably learning and memory.

SIGNAL TRANSDUCTION PATHWAYS

Signal transduction **refers to the processes by which extracellular stimuli are transferred to—and propagated as—intracellular signals (Figure 1–11). Multicomponent cellular-signaling pathways interact at various levels, thereby forming complex networks that allow the cell to receive, process, and respond to information (Bhalla and Iyengar 1999; Bourne and Nicoll 1993). These networks facilitate the integration of signals across multiple time scales, the generation of distinct outputs that depend on input strength and duration, and the regulation of intricate feed-forward and feedback loops (Bhalla and Iyengar 1999). These properties of signaling networks suggest that they play critical roles in cellular memory; thus, cells with different histories, and therefore expressing different repertoires of signaling molecules, interacting at different levels, may respond quite differently to the same signal over time. Given their widespread and crucial role in the integration, regulation, amplification, and fine-tuning of physiological processes, it is not surprising that abnormalities in signaling pathways have now been identified in a variety of human diseases (Simonds 2003; Spiegel 1998). Pertinent to the present discussion is the observation that a variety of diseases manifest a relatively circumscribed symptomatology, despite the widespread, often ubiquitous expression of the affected signaling proteins.**

FIGURE 1–11. Principles of signal transduction.

As described in the text, neurons regulate signaling pathways through multiple mechanisms and at multiple levels. Neuronal circuits possess a large number of extracellular neuroactive molecules **(1; labeled A, B, and C)** that can interact with multiple receptors **(2).** Binding of neuroactive molecules to receptors can result in stimulation and/or attenuation of multiple cellular signaling pathways **(3),** depending on the type of receptor, location in the central nervous system, and activity of other signaling pathways within the cell. Thus, the potential is there to greatly amplify the signals. This signaling can then converge on one signaling pathway **(4)** or diverge into many signaling pathways **(5).** Activation of signaling pathways alters gene transcription and activity of proteins such as ion channels and other signaling molecules **(6).** Additionally, activation of signaling pathways can both positively **(7)** and negatively **(8)** regulate the function of extracellular receptors. Bcl-2 = an anti-apoptotic protein; BDNF = brain-derived neurotrophic factor; CREB = cAMP response element–binding protein.

Although complex signaling networks are likely present in all eukaryotic cells and control various metabolic, humoral, and developmental functions, they may be especially important in the CNS, where they serve the critical roles of first amplifying and "weighting" numerous extracellularly generated neuronal signals and then transmitting these integrated signals to effectors, thereby forming the basis for a complex information-processing network (Bourne and Nicoll 1993; Manji 1992). The high degree of complexity generated by these signaling networks may be one mechanism by which neurons acquire the flexibility for generating the wide range of responses observed in the nervous system. These pathways are thus undoubtedly involved in regulating such diverse vegetative functions as mood, appetite, and wakefulness and are therefore likely to be involved in the pathophysiology of a variety of psychiatric disorders and their treatments.

G Proteins

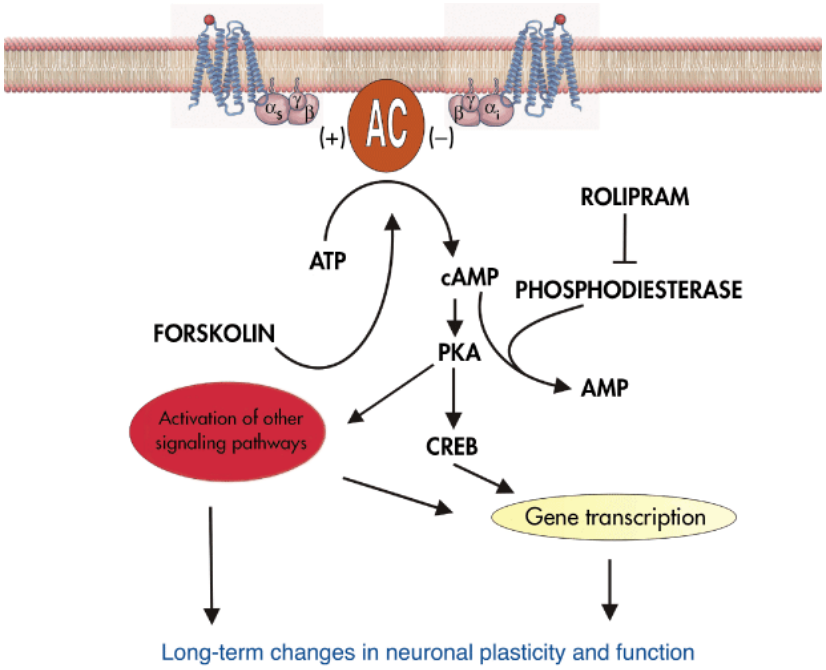
As mentioned already, G proteins were originally named because of their ability to bind the guanine nucleotides guanosine triphosphate and guanosine diphosphate. Receptors coupled to G proteins include those that respond to catecholamines, serotonin, ACh, various peptides, and even sensory signals such as light and odorants. G_s and G_i were among the first G proteins identified and received their names because of their ability to stimulate or inhibit adenylyl cyclase. Since that time, a multitude of G protein subunits have been identified by a combination of biochemical and molecular cloning techniques. Indeed, genes for 16 $G\alpha$ subunits are known and give rise via alternative splicing to at least 20 mature $G\alpha$ subunits with differential tissue expression (Simonds 2003) (see Table 1–1). There are four homology-based subfamilies of $G\alpha$ subunits: the G_s subfamily, whose members stimulate adenylyl cyclase; the G_i subfamily, which includes G_{i1-3} and G_z, which inhibit adenylyl cyclase; the G_q subfamily, whose members activate PLC-β; and the G_{12} subfamily, whose members interact with regulators of G protein signaling (RGS) domain–containing Rho exchange factors (see Table 1–1 and Figure 1–2) (Simonds 2003). Genes encoding 5 $G\beta$ isoforms and 12 different $G\gamma$ subunits are known in humans; effectors of $G\beta\gamma$ complexes include ion channels, isoforms of adenylyl cyclase, isoforms of PLC-β, and MAP kinase pathways (Simonds 2003) (see Table 1–1).

G Protein Function

G proteins function in the context of two interrelated cycles: a cycle of subunit association and dissociation and a cycle of GTP binding and hydrolysis (discussed in detail in the legend to Figure 1–2). G protein heterotrimers consist of $G\alpha$, $G\beta$, and $G\gamma$ subunits at a 1:1:1 stoichiometry and are named according to decreasing mass, with the α subunits having an apparent mass of 40–52 kDa, β subunits having an apparent mass of 35–36 kDa, and γ subunits having an apparent mass of 5–20 kDa. The different types of G protein have been named on the basis of the distinct α subunits they possess (i.e., G_s represents G proteins containing $G\alpha_s$). This classification system arose from the erroneous assumption that it was only the α subunits that were responsible for the proteins' specific functional activity; it is now known that the β and γ subunits exert a number of functional effects on their own (see Table 1–1) and are not simply "anchoring proteins" for α subunits. Although the β and γ subunits are not covalently bound, they are tightly linked by noncovalent coiled-coil interactions; thus, they are generally assumed to function as $\beta\gamma$ dimers. It is very likely that different $\beta\gamma$ subunits exert different effects on α subunits and effectors (e.g., $\beta_2\gamma_2$ behaves differently from $\beta_2\gamma_3$), but the delineation of the differential effects of the different subunit compositions is still in its infancy.

Mediation of neurotransmitter–neurotransmitter and receptor–receptor interactions

The CNS is remarkably complex, both anatomically and chemically, with a remarkable convergence of different receptors in common cortical layers and considerable convergence of neurotransmitter action. A single neuron in the brain receives thousands of synaptic inputs on the cell body and dendrites, and neuronal response is also modulated by a variety of hormonal and neurohormonal substances that are not dependent on synaptic organization (Kandel et al. 2000). The neuron needs to integrate all the synaptic and nonsynaptic inputs impinging on it; this integration of a multitude of signals determines the ultimate excitability, firing pattern, and response characteristics of the neuron, which are then conveyed to succeeding targets via synaptic transmission. How does the single neuron decipher and integrate the multitude of signals it receives and, additionally, generate unique responses to each of these signals or combinations of signals?



Not only do G proteins amplify signals, but they also appear to form the basis of a complex information-processing network in the plasma membrane (Bhalla and Iyengar 1999; Manji 1992). Thus, the ability of G proteins to interact with multiple receptors provides an elegant mechanism to organize the signals from these multiple receptors and to transmit them to a relatively much smaller number of effectors. Signals from a variety of receptors can be "weighted" according to their intrinsic ability to activate a given G protein and integrated to stimulate a single second-messenger pathway (see Figure 1–11). Similarly, the dual (positive and negative) regulation of adenylyl cyclase by G proteins allows for stimulatory and inhibitory signals for these pathways to be "balanced" at the G protein level, yielding an integrated output. Thus, G proteins provide the first opportunity for signals from different receptors to be integrated. This complex web of interactions linking receptors, G proteins, and their effectors with signals converging to shared detectors appears to be crucial for the integrative functions performed by the CNS.

Abnormalities in a variety of human diseases have now been clearly shown to arise from primary abnormalities in G protein signaling cascades and in the G protein subunits themselves (for an excellent discussion, see Simonds 2003; Spiegel 1998). To date, the direct evidence for the involvement of G proteins in psychiatric disorders is more limited. Thus, although elevations in the levels of $G\alpha_s$ have been found in postmortem brain and peripheral tissue in bipolar disorder, a mutation in the $G\alpha_s$ gene has not yet been identified (discussed in Manji and Lenox 1999). There is, however, convincing evidence that chronic lithium administration attenuates the functioning of both G_s and G_i, resulting in an elevation of basal cAMP levels but dampened receptor-mediated effects. The allosteric modulation of G proteins has been proposed to play a role in lithium's long-term prophylactic efficacy in protecting susceptible individuals from cyclic affective episodes induced spontaneously or by stress or drugs (e.g., antidepressant, stimulant) (G. Chen et al. 1999; Gould and Manji 2002).

The cAMP signaling cascade

G proteins control intracellular cAMP levels by mediating the ability of neurotransmitters to activate or inhibit adenylyl cyclase (Figure 1–12; see also Figure 1–2). The mechanism by which neurotransmitters stimulate adenylyl cyclase is well established. Activation of those neurotransmitter receptors that couple to G_s results in the generation of free $G\alpha_s$ subunits that bind to and directly activate adenylyl cyclase. A similar mechanism appears to be the case for $G\alpha_{olf}$, a type of G protein (structurally related to $G\alpha_s$) that is enriched in olfactory epithelium and dopamine-rich areas of the brain and mediates the ability of odorant receptors and D_1 receptors to stimulate adenylyl cyclase. The mechanism by which neurotransmitters inhibit adenylyl cyclase and decrease neuronal levels of cAMP is somewhat less clear, and more than one mechanism may be operative. By analogy with the action of G_s, it was originally proposed that activation of neurotransmitter receptors that couple to Gi results in the generation of free $G\alpha_i$ subunits, which could bind to, and thereby directly inhibit, adenylyl cyclase. While this mechanism may be operative, there are also data to suggest that $\beta\gamma$ subunit complexes, generated by the release of $G\alpha_i$, might directly inhibit certain forms of adenylyl cyclase or might bind and "tie up" free $G\alpha_s$ subunits in the membrane.

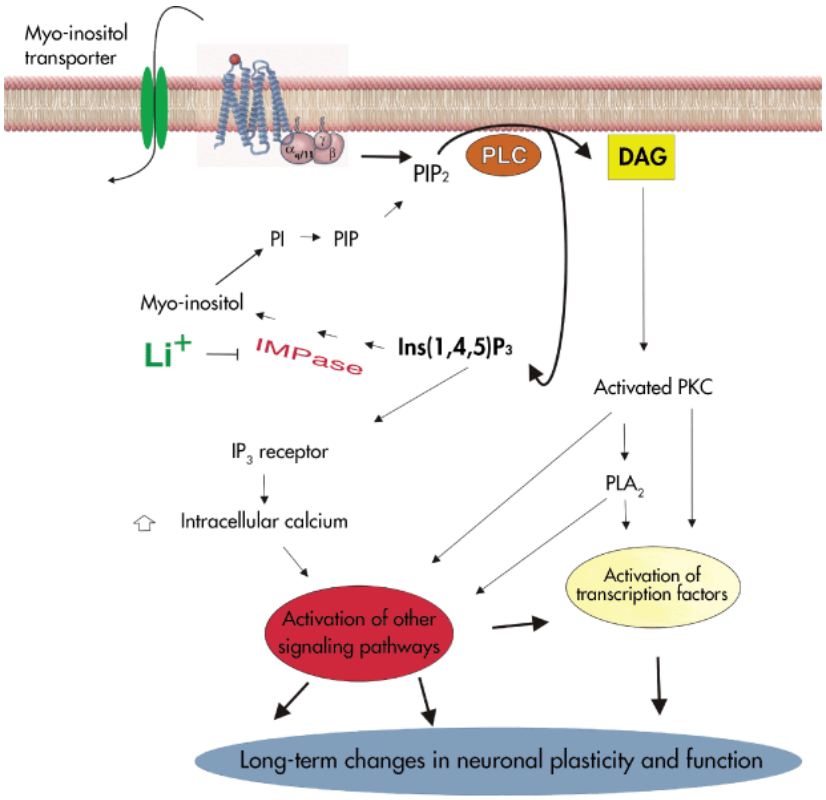
Receptors can be positively (e.g., β-adrenergic, D_1) or negatively (e.g., 5-HT_{1A}, D_2) coupled to adenylyl cyclase (AC) to regulate cAMP levels. The effects of cAMP are mediated largely by activation of protein kinase A (PKA). One major downstream target of PKA is CREB (cAMP response element–binding protein). After activation, the phosphorylated CREB binds to the cAMP response element (CRE), a gene sequence found in the promoter of certain genes; data suggest that antidepressants may activate CREB, thereby bringing about increased expression of a major target gene, BDNF. Phosphodiesterase is an enzyme that breaks down cAMP to AMP. Some antidepressant treatments have been found to upregulate phosphodiesterase. Drugs like rolipram, which inhibit phosphodiesterase, may be useful as adjunct treatments for depression. Forskolin is an agent used in preclinical research to stimulate adenylyl cyclase.

It is now clear that there are several forms of adenylyl cyclase that make up a distinct enzyme family; these various forms are differentially regulated and display distinct distributions in nervous and nonnervous tissues. For example, type I is found predominantly in brain, whereas types II and IV, although abundantly expressed in the brain, have a more widespread distribution. The topographical structure of the adenylyl cyclase proteins resembles that of

membrane transporters and ion channels. However, there is currently no convincing evidence of a transporter or channel function for mammalian adenylyl cyclases.



As would be predicted, the different forms of adenylyl cyclase are regulated by distinct mechanisms. Type I through IV enzymes differ in their ability to be regulated by Ca^{2+} and calmodulin. Types I and III are stimulated by Ca^{2+}-calmodulin complexes, whereas types II and IV are insensitive. Perhaps the most intriguing regulation is that by the G protein β and γ subunits. Thus, it is now clear that when type II adenylyl cyclase is concurrently stimulated by a stimulatory receptor (e.g., β-adrenergic receptor), the βγ subunits released from an "inhibitory receptor" (e.g., 5-HT_{1A}, α_2, $GABA_B$) can, in fact, *robustly potentiate* the cAMP response (Bourne and Nicoll 1993). Type II adenylyl cyclase thus serves as a "coincidence detector" in the CNS, capable of temporally and spatially integrating signals to bring about dramatically different effects. An additional important mechanism by which adenylyl cyclase can be regulated is by cross-talk with protein kinase C, thereby linking receptors linked to stimulation of adenylyl cyclase and those linked to the turnover of membrane phosphoinositides. The physiological effects of cAMP are mediated primarily by activation of protein kinase A, an enzyme that phosphorylates and regulates many proteins, including ion channels, cytoskeletal elements, transcription factors, and other enzymes. Indeed, one major CNS target for the actions of PKA is the transcription factor CREB (cAMP response element–binding protein), which plays a major role in long-term neuroplasticity and is an indirect target of antidepressants (Duman 2002) (see Figure 1–12). As we discuss in greater detail below, phosphorylation and dephosphorylation reactions play a major role in regulating a variety of long-term neuroplastic events in the CNS.

Phosphoinositide / Protein Kinase C

Phosphoinositide

Although inositol phospholipids are relatively minor components of cell membranes, they play a major role in receptor-mediated signal transduction pathways. They are involved in a diverse range of responses, such as cell division, secretion, and neuronal excitability and responsiveness. In many cases, $G_{q/11}$ is involved, and it is believed that $G\alpha_{q/11}$ directly binds to and activates phospholipase C (Figure 1–13). In other cases, however, it is the βγ subunits released upon activation of receptors coupled to G_i/G_o that bring about activation of the enzyme PLC to produce the intracellular second messengers sn-1,2-diacylglycerol (DAG; an endogenous activator of PKC) and inositol-1,4,5-triphosphate (IP_3). IP_3 binds to the IP_3 receptor and facilitates the release of calcium from intracellular stores, in particular the endoplasmic reticulum (see Figure 1–13). The released calcium then interacts with various proteins in the cell, including the important family of calmodulins (Ca^{2+}-receptor protein calmodulin, or CaM) (discussed later in this chapter; Figure 1–14). Calmodulins then activate calmodulin-dependent protein kinases (CaMKs), which affect the activity of diverse proteins, including ion channels, signaling molecules, proteins that regulate apoptosis, scaffolding proteins, and transcription factors (Miller 1991; Soderling 2000).

A number of receptors in the CNS (including M_1, M_3, M_5, 5-HT_{2C}) are coupled, via $G\alpha_{q/11}$, to activation of PI hydrolysis. Activation of these receptors induces phospholipase C (PLC) hydrolysis of phosphoinositide-4,5-bisphosphate (PIP_2) to sn-1,2-diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP_3). DAG activates protein kinase C (PKC), an enzyme that has many effects, including the activation of phospholipase A_2 (PLA_2), an activator of arachidonic acid signaling pathways. IP_3 binds to the IP_3 receptor, which results in the release of intracellular calcium from intracellular stores, most notably the endoplasmic reticulum. Calcium is an important signaling molecule and initiates a number of downstream effects such as activation of calmodulins and calmodulin-dependent protein kinases (see Figure 1–15). IP_3 is recycled back to PIP_2 by the enzymes inositol monophosphatase (IMPase) and inositol polyphosphatase (IPPase; not shown), both of which are targets of lithium. Thus, lithium may initiate many of its therapeutic effects by inhibiting these enzymes, thereby bringing about a cascade of downstream effects involving PKC and gene expression changes.

In neurons, Ca^{2+}-dependent processes represent an intrinsic nonsynaptic feedback system that provides competence for adaptation to different functional tasks. Ca^{2+} is generally mobilized in one of two ways in the cells: either by mobilization from intracellular stores (e.g., from the endoplasmic reticulum) or from outside of the cell via plasma membrane ion channels and certain receptors (e.g., NMDA [*N*-methyl-D-aspartate]). The external concentration of Ca^{2+} is approximately 2 mM, yet resting intracellular Ca^{2+} concentrations are in the range of 100 nM (2×10^4 *lower*). Local high levels of calcium result in activation of enzymes, signaling cascades, and, at extremes, cell death. Release of intracellular stores of calcium is primarily regulated by inositol-1,4,5-triphosphate (IP_3) receptors that are activated upon generation of IP_3 by phospholipase C (PLC) activity, and the ryanodine receptor that is activated by the drug ryanodine. Many proteins bind Ca2+ and are classified as either "buffering" or "triggering." These include calcium pumps, calbindin, calsequestrin, calmodulin, PKC, phospholipase A_2, and calcineurin. Once stability of intracellular calcium is accomplished, transient low-magnitude changes can serve an important signaling function. Calcium action is *local*. Because of the high concentration of calcium-binding proteins, it is estimated that the free Ca^{2+} ion diffuses only approximately 0.5 μM and is free for about 50 μsec before encountering a Ca^{2+}-binding protein. Ca^{2+} is sequestered in the endoplasmic reticulum (which serves as a vast web and framework for Ca2+-binding proteins to capture and sequester Ca^{2+}). Ca^{2+} buffering/triggering proteins are nonuniformly distributed, so there is considerable subcellular variation of Ca^{2+} concentrations (e.g., near a Ca^{2+} channel). The primary mechanism for Ca^{2+} calcium exit from the cell is either via sodium-calcium exchange or by means of a calcium pump.

IP_3 can be metabolized both by dephosphorylation to form inositol-1,4-P_2 and by phosphorylation to form inositol-1,3,4,5-P_4 (IP_4), which has been proposed to be involved in the entry of Ca^{2+} into cells from extracellular sources. Recycling of IP_3 is important for continuation of phosphoinositide hydrolysis in response to extracellular signals. This is achieved by the enzyme inositol monophosphatase (IMPase), which is the rate-limiting enzyme that converts IP_3 back to phosphoinositide-4,5-bisphosphate (PIP_2). Without this enzyme, PIP_2 cannot be recycled adequately, potentially leading to low levels of PIP_2 and inhibition of the signaling cascades involving DAG and IP_3. Lithium, at therapeutically relevant concentrations, is a noncompetitive inhibitor of IMPase (for a review, see Gould et al. 2003). This has led to the "inositol depletion hypothesis," which posits that lithium brings about a reduction in the levels of inositol by inhibiting the activity of this "recycling enzyme." Although lithium does reduce inositol levels in the areas of the brain in bipolar patients (Moore et al. 1999), this likely represents an upstream "initiating event," which brings about downstream changes in PKC and regulates gene expression, which may be ultimately responsible for some of its therapeutic effects (see Figure 1–13) (Brandish et al. 2005; Gould et al. 2003; Manji and Lenox 1999).

Protein Kinase C

Ca^{2+}-activated, phospholipid-dependent protein kinase (protein kinase C, or PKC) is a ubiquitous enzyme, highly enriched in brain, where it plays a major role in regulating both pre- and postsynaptic aspects of neurotransmission (Nishizuka 1992; Stabel and Parker 1991). PKC is one of the major intracellular mediators of signals generated upon external stimulation of cells via a variety of neurotransmitter receptors (including muscarinic [M_1, M_3, M_5], noradrenergic [α_1], and serotonergic [5-HT_2] receptors) that induce the hydrolysis of various membrane phospholipids.

Activation of PKC by DAG appears to involve the binding of the lipid to a specific regulatory site on the enzyme, resulting in an increase in the Ca^{2+} affinity, and thus its stimulation at physiological ionic concentrations. Ca^{2+} is also believed to contribute to PKC activation by facilitating the interaction of the enzyme with the lipid bilayer and hence with acidic phospholipids and DAG. PKC is now known to exist as a family of closely related subspecies, has a heterogeneous distribution in brain (with particularly high levels in presynaptic nerve terminals), and, together with other kinases, appears to play a crucial role in the regulation of synaptic plasticity and various forms of learning and memory. The multiple closely related PKC isoforms are all activated by

phospholipids and DAG, albeit with slightly different kinetics. The isoforms can be subclassified according to Ca^{2+} dependence: the "conventional" PKCs (α, βI, βII, γ) are dependent on Ca^{2+} for activity, whereas several others, termed "novel" (δ, ε, η, θ) and "atypical" (ζ, λ, ξ), are calcium independent (Nishizuka 1992). The conventional, novel, and atypical isozymes all share activation by phospholipids or DAG and an autoinhibitory pseudosubstrate region, which maintains the enzyme in an inactive state until activated. However, the subgroups are activated by different activators. The conventional PKCs require calcium, acidic phospholipids, and DAG for activation; the novel PKCs do not require calcium, and the atypical PKCs do not require calcium or DAG. PKC isozymes that do not share the pseudosubstrate region (μ/PKD and ν) have been described, which suggests a possible different mode of action.

The differential tissue distribution of PKC isozymes, as well as the fact that several isoforms are expressed within a single cell type, suggests that each isozyme may exert distinct cellular functions. At present, it is unclear whether such putative functional specificity arises from differential in vivo activation, differential substrate specificity, or a combination thereof. PKC has many growth-regulating properties in immature cells and has additional cell-specific responses in individual mature cells (Kanashiro and Khalil 1998). One protein whose activity is modulated by PKC is myristoylated alanine-rich C kinase substrate (MARCKS). This protein functions as a regulated crossbridge between actin and the plasma membrane, contributing to the cytoskeleton of the cell and subsequently to neuronal plasticity (Aderem 1992) (see Figure 1–13). PKC is also an important activator of phospholipase A_2, thus linking the phosphoinositide cycle with arachidonic acid pathways (see Figure 1–13). Arachidonic acid functions as an important mediator of second-messenger pathways within the brain and is regulated by chronic lithium (Axelrod et al. 1988; Rapoport 2001). The activation of phospholipase A_2 by PKC (and other pathways) results in arachidonic acid release from membrane phospholipids (Axelrod 1995). This release of arachidonic acid from cellular membrane allows for the subsequent formation of a number of eicosanoid metabolites such as prostaglandins and thromboxanes. These metabolites mediate numerous subsequent intracellular responses and, because of their lipid permeable nature, transsynaptic responses.

PKC also has been demonstrated to be active in many other cellular processes, including stimulation of transmembrane glucose transport, secretion, exocytosis, smooth muscle contraction, gene expression, modulation of ion conductance, cell proliferation, and desensitization of extracellular receptors (Nishizuka 1992). One of the best-characterized effects of PKC activation in the CNS is the facilitation of neurotransmitter release. Studies have suggested that PKC activation may facilitate neurotransmitter release via a variety of mechanisms, including modulating several ionic conductances regulating Ca^{2+} influx, upstream steps regulating release of Ca^{2+} from intracellular stores, recruitment of vesicles to at least two distinct vesicle pools, and the Ca^{2+} sensitivity of the release process itself (discussed in Bown et al. 2002). Abundant data also suggest that the PKC signaling pathway may play an important role in the pathophysiology and treatment of bipolar disorder (Manji and Lenox 1999). Thus, elevations in PKC isozymes have been reported in postmortem brain and platelets in bipolar patients; more importantly, in animal and cell-based models, lithium and valproate exert strikingly similar effects on PKC isozymes and substrates in a time frame mimicking their therapeutic actions.

A recent whole-genome association study of bipolar disorder has further implicated this pathway. Of the risk genes identified, the one demonstrating by far the strongest association with bipolar disorder was diacylglycerol kinase, an immediate regulator of PKC (Baum et al. 2008). In animal models of mania, several studies have demonstrated that both acute and chronic amphetamine exposure produces an alteration in PKC activity and its relative cytosol-to-membrane distribution, as well as the phosphorylation of a major PKC substrate, GAP-43, which has been implicated in long-term alterations of neurotransmitter release. Increased hedonistic drive and increased tendency to abuse drugs are well-known facets of manic behavior; notably, PKC inhibitors attenuate these important aspects of the manic-like syndrome in rodents (Einat and Manji 2006; Einat et al. 2007). Recent preclinical studies have specifically investigated the antimanic effects of tamoxifen (since this is the only CNS-penetrant PKC inhibitor available for humans). These studies showed that tamoxifen significantly reduced amphetamine-induced hyperactivity and risk-taking behavior (Einat et al. 2007). Finally, with respect to cognitive dysfunction associated with mania, Birnbaum et al. (2004) demonstrated that excessive activation of PKC dramatically impaired the cognitive functions of the prefrontal cortex and that inhibition of PKC protected cognitive function. In summary, preclinical biochemical and behavioral data support the notion that PKC activation may result in manic-like behaviors, whereas PKC inhibition may be antimanic. These preclinical data, along with animal studies discussed above, have prompted clinical studies of PKC inhibitors and mood dysregulation. A number of small studies have found that tamoxifen, a nonsteroidal antiestrogen and a PKC inhibitor at high concentrations, possesses antimanic efficacy (Bebchuk et al. 2000; Kulkarni et al. 2006). Most recently, a double-blind, placebo-controlled trial of tamoxifen in the treatment of acute mania was undertaken (Zarate et al. 2007). Subjects showed significant improvement in mania on tamoxifen compared with placebo as early as 5 days, and the effect size for the drug difference was very large after 3 weeks.

Calcium

Calcium is a very common signaling element and plays a critical role in the CNS by regulating the activity of diverse enzymes and facilitating neurotransmitter release (see Figure 1–14). Importantly, excessively high levels of calcium are also a critical mediator of cell death cascades within neurons, necessitating diverse homeostatic mechanisms to regulate intracellular calcium levels very precisely. Thus, although the external level of Ca2+ is approximately 2 mM, the resting intracellular Ca2+ concentrations (Ca^{2+}_i) are in the range of 100 nM (that is, 2×10^4 *lower*) (Rasmussen 1989). Neuronal stimulation by depolarization or receptor activation activates phosphoinositol turnover and increases Ca^{2+}_i by one to two orders of magnitude as a result of release of Ca^{2+} from intracellular stores and/or influx of Ca^{2+} through ion channels (Rink 1988). Acting via intracellular proteins such as calmodulin and enzymes such as PKC, calcium ions influence synthesis and release of neurotransmitters (Parnas and Segel 1989), receptor signaling (Rasmussen 1986), and neuronal periodicity (Matthews 1986).

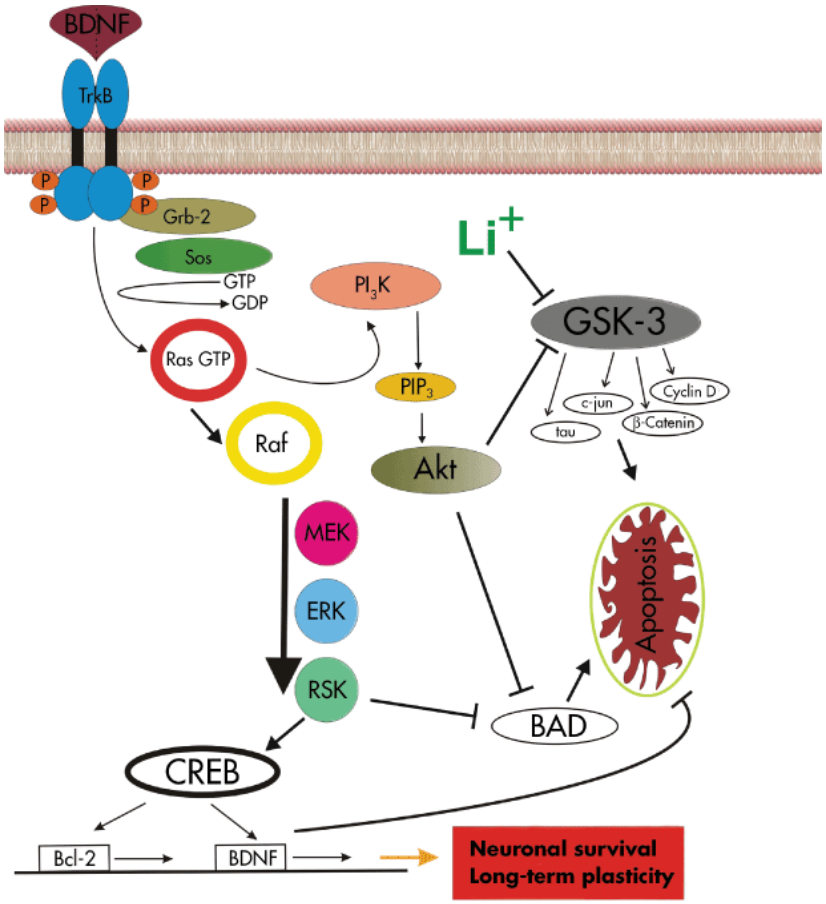
Many proteins bind Ca^{2+}; these are classified as either "buffering" or "triggering" and include calcium pumps, calbindin, calsequestrin, calmodulin, PKC, phospholipase A_2, and calcineurin (see Figure 1–14). Once stability of intracellular calcium is accomplished, transient low-magnitude changes can serve an important signaling function. Importantly, calcium action is locally mediated; that is, because of the high concentration of calcium-binding proteins, it is estimated that the free Ca^{2+} ion diffuses only approximately 0.5 μM and is free for around 50 μsec before encountering a Ca^{2+}-binding protein. Ca^{2+} is sequestered in the endoplasmic reticulum (which serves as a vast web and framework for Ca^{2+}-binding proteins to capture and sequester Ca^{2+}). Ca^{2+} buffering/triggering proteins are nonuniformly distributed, and thus there is considerable subcellular variation of Ca^{2+} concentrations (e.g., near a Ca^{2+} channel).

Calcium is generally mobilized in one of two ways in the cell, either by mobilization from intracellular stores or by selective diffusion across plasma membrane ion channels (see Figure 1–14). Ca^{2+} ions pass the membrane through more or less specific channels regulated by changes of membrane potential or transmitter binding. This Ca^{2+} influx lasts until Ca^{2+} levels reach a critical level in the submembranal compartment; a potassium current is then activated that repolarizes the membrane. This Ca^{2+}-dependent potassium current represents a strong inhibitory mechanism of the single neuron itself without synaptic input. Its attractiveness for psychiatry lies in its sensitivity to modulatory influences: many amines, peptides, or drugs with relevance in the etiology and/or treatment of these disorders (e.g., norepinephrine, dopamine, corticotrophin-releasing factor [CRF], caffeine, neuroleptics) modify (i.e., increase or decrease) this potassium current. When activation of the potassium pump is decreased, the capacity for negative feedback after excitation becomes impaired and the neuron switches to a state of higher activation, coincidentally with increased calcium influx. Such an overdrive in calcium currents and discharge activity could be a functional prerequisite for states of pathological activity, possibly underlying neuropsychiatric symptoms such as epilepsy, mania, or depression.

Ca^{2+} released intracellularly is regulated both positively and negatively, resulting in the generation of dynamic Ca^{2+} waves. Once intracellular Ca^{2+} levels are increased, this triggers/activates a number of proteins (e.g., adenylyl cyclase type I, CaMKs, PKC, calpain [a protease], calcineurin [a protein phosphatase]). In neurons, Ca^{2+}-dependent processes represent an intrinsic nonsynaptic feedback system that provides the competence for adaptation to

different functional tasks (see Figure 1–14). Regulation of intracellular Ca^{2+} could be of particular relevance to the study of psychiatric disorders, because the same elevation of intracellular Ca^{2+} may facilitate or inhibit a given function, depending on the target enzyme, the phase of the cell cycle, the intracellular effector protein, and the Ca^{2+}-dependent process. In addition, higher or more sustained increases of intracellular Ca^{2+} may inhibit the same function that smaller elevations facilitate (Wolff et al. 1977), so that elevated intracellular Ca^{2+} can produce excessive activation of some systems and inhibition of others. A polymorphism in PPP3CC, a component of the calcium-dependent protein phosphatase calcineurin, has been associated with risk of developing schizophrenia in at least two patient populations (Gerber et al. 2003; Y. L. Liu et al. 2007).

Signaling Cascades Generally Utilized by Neurotrophic Receptors in the CNS



The pleiotropic and often profound effects (e.g., neuronal growth, differentiation, survival) of neurotrophins and growth factors in the CNS are generally mediated by varying degrees of activation of three major signaling pathways: MAP kinase (extracellular response kinase [ERK]) pathway, the phosphoinositol-3 kinase pathway, and the phospholipase C–γ1 pathway (see Figure 1–9). Among these pathways, the effects of the PI_3K pathway and the MAP kinase pathway have been most directly linked to the cell survival effects of neurotrophins (Patapoutian and Reichardt 2001).

MAP Kinase Cascade

MAP kinases are abundantly present in brain and have been postulated to play a major role in a variety of long-term CNS functions, in both the developing and the mature CNS (Fukunaga and Miyamoto 1998; Kornhauser and Greenberg 1997; Matsubara et al. 1996; Robinson et al. 1998). With respect to their actions in the mature CNS, MAP kinases have been implicated in mediating neurochemical processes associated with long-term facilitation (Martin et al. 1997), long-term potentiation (English and Sweatt 1996, 1997), associative learning (Atkins et al. 1998), one-trial and multitrial classical conditioning (Crow et al. 1998), long-term spatial memory (Blum et al. 1999), and modulation of the addictive effects of abused drugs (Lu et al. 2005). They have also been postulated to integrate information from multiple infrequent bursts of synaptic activity (Murphy et al. 1994). Importantly for the present discussion, MAP kinase pathways have been demonstrated to regulate the responses to environmental stimuli and stressors in rodents (Xu et al. 1997) and to couple PKA and PKC to CREB protein phosphorylation in area CA1 of the hippocampus (Roberson et al. 1996, 1999). These studies suggest the possibility of a broad role for the MAP kinase cascade in regulating gene expression in long-term forms of synaptic plasticity (Roberson et al. 1999). For example, it has recently been shown that CREB modulates excitability of neurons of the nucleus accumbens, which helps to limit behavioral sensitivity to cocaine in rodent models (Dong et al. 2006). Thus, overall, the data suggest that MAP kinases play important physiological roles in the mature CNS and, furthermore, may be important targets for the actions of CNS-active agents (Nestler 1998).

Growth factors acting through specific receptors (e.g., BDNF acting on TrkB) activate the Ras/MAP kinase signaling cascade (Figure 1–15). Among the targets of the MAP kinase pathway is ribosomal S6 kinase (RSK). RSK phosphorylates CREB and other transcription factors. Studies have demonstrated that the activation of the MAP kinase pathway can inhibit apoptosis by inducing the phosphorylation and inactivation of the pro-apoptotic protein BAD (Bcl-xl/Bcl-2–associated death promoter) and increasing the expression of the anti-apoptotic protein Bcl-2 (the latter effect likely involves CREB) (Bonni et al. 1999; Riccio et al. 1997). Phosphorylation of BAD occurs via activation of RSK. RSK phosphorylates BAD and thereby promotes its inactivation. Activation of RSK also mediates the actions of the MAP kinase cascade and neurotrophic factors on the expression of Bcl-2. RSK can phosphorylate CREB, leading to the expression of genes with neurotrophic functions, such as Bcl-2 and BDNF (see Figure 1–15). Treatment with mood-stabilizing drugs activates the ERK (extracellular signal–related kinase) pathway in brain regions involved in mood regulation (reviewed in G. Chen and Manji 2006). Earlier work showed that lithium and valproate induce AP-1 and CREB transcription factors and enhance expression of the bcl-2 gene. Later, it was found that chronic lithium or valproate treatment promotes neurogenesis in the hippocampus, an effect mediated at least in part by activation of the ERK pathway (see G. Chen and Manji 2006).

The influence of neurotrophic factors on cell survival is mediated by activation of the MAP kinase cascade and other neurotrophic cascades. Activation of neurotrophic factor receptors referred to as tyrosine receptor kinases (Trks) results in activation of the MAP kinase cascade via several intermediate steps, including phosphorylation of the adaptor protein Shc and recruitment of the guanine nucleotide exchange factor Sos. This results in activation of the small guanosine triphosphate–binding protein Ras, which leads to activation of a cascade of serine/threonine kinases. This includes Raf, MAP kinase kinase (MEK), and MAP kinase (also referred to as extracellular response kinase, or ERK). One target of the MAP kinase cascade is the ribosomal S6 kinases, known as RSK, which influences cell survival in at least two ways. RSK phosphorylates and inactivates the pro-apoptotic factor BAD (Bcl-xl/Bcl-2–associated death promoter). RSK also phosphorylates cAMP response element–binding protein (CREB) and thereby increases the expression of the anti-apoptotic factor Bcl-2 and brain-derived neurotrophic factor (BDNF). Ras also activates the phosphoinositol–3 kinase (PI_3K) pathway, a primary target of which is the enzyme glycogen synthase kinase (GSK-3). Activation of the PI_3 kinase pathway deactivates GSK-3. GSK-3 has multiple targets in cells, including transcription factors (β-catenin and c-Jun) and cytoskeletal elements such as tau. Many of the targets of GSK-3 are pro-apoptotic when activated. Thus, deactivation of GSK-3 via activation of the PI_3K pathway results in neurotrophic effects. Lithium inhibits GSK-3, an effect that may be, at least in part, responsible for lithium's therapeutic effects. These mechanisms underlie many of the long-term effects of neurotrophins, including neurite outgrowth, cytoskeletal remodeling, and cell survival.

Inactivation of the ERK pathway in the CNS induces animal behavioral alterations reminiscent of manic symptoms, which are likely to depend on ERK's effect on distinct brain regions and the presence of interacting molecules (Shaltiel et al. 2007). Moreover, ERK knockout mice display behavioral abnormalities related to manic symptoms. These data support a clinical role for the ERK pathway in therapeutic action of mood stabilizers. Nevertheless, the possible role of this pathway in the pathophysiology of bipolar disorder has yet to be elucidated.

PI_3 Kinase–Akt Pathway

The PI_3K–Akt pathway is also particularly important for mediating neuronal survival in a wide variety of circumstances. Trk receptors can activate PI_3K through at least two distinct pathways, the relative importance of which differs between neuronal subpopulations. In many neurons, Ras-dependent activation of PI_3K is the most important pathway through which neurotrophins promote cell survival (see Figure 1–15). In some cells, however, PI_3K can also be activated through three adaptor proteins: Shc, Grb-2, and Gab-1. Binding to phosphorylated tyrosine 490 of Shc results in recruitment of Grb-2 (see Figure 1–9). Phosphorylated Grb-2 provides a docking site for Gab-1, which in turn is bound by PI_3K (Brunet et al. 2001). PI_3K directly regulates certain cytoplasmic apoptotic pathways. Akt has been proposed to act both prior to the release of cytochrome c by pro-apoptotic Bcl-2 family members and subsequent to the release of cytochrome c by regulating components of the apoptosome. Akt phosphorylates the pro-apoptotic Bcl-2 family member BAD, thereby inhibiting BAD's pro-apoptotic functions (see Figure 1–15) (Datta et al. 1997).

Another important target of Akt is the enzyme glycogen synthase kinase–3 (GSK-3) (see Figures 1–11 and 1–15). GSK-3 is a serine/threonine kinase that is, in general, constitutively active in cells. It is found in two forms—α and β—and currently appears to be the only kinase significantly *directly* inhibited by lithium (Davies et al. 2000; Klein and Melton 1996; Stambolic et al. 1996). It may thus represent a target of the development of novel medications for the treatment of bipolar disorder (Gould and Manji 2005). While most research has focused on the β isoform, available evidence suggests that the two forms may have very similar—though not absolutely identical—biological properties (Ali et al. 2001; Plyte et al. 1992). GSK-3 was named on the basis of its originally described function as a kinase that inactivates glycogen synthase. Following insulin receptor stimulation, PI_3K and Akt are activated, and this results in the phosphorylation and concomitant inactivation of GSK-3. Inactivated GSK-3 no longer phosphorylates glycogen synthase, allowing the formation of glycogen from glucose (Cohen and Frame 2001; Woodgett 2001).

In addition to regulation by Akt, other kinases, including p70 S6 kinase, RSK, and cAMP-dependent protein kinase (PKA), appear to deactivate GSK-3 by phosphorylation (Cohen and Frame 2001; Grimes and Jope 2001). The effect of GSK-3 on transcription factors such as c-Jun, heat shock factor–1 (HSF-1), nuclear factor of activated T-cells (NFAT), and β-catenin (see below) has drawn considerable interest and is particularly noteworthy (Frame and Cohen 2001; Grimes and Jope 2001) (see Figure 1–15). Generally, GSK-3 activity results in suppression of the activity of transcription. Conversely, inactivation of GSK-3 appears to activate these transcription factors (Grimes and Jope 2001). Thus, GSK-3 is well positioned to receive signals from multiple diverse signal pathways, a function that is undoubtedly critical in the CNS.

GSK-3 is also a critical regulator of the Wnt pathway. Wnt is a family of secreted glycoproteins that are well known to have important roles in development. Signaling through Wnt glycoproteins results in inactivation of GSK-3 and a subsequent increase in the transcription factor β-catenin. Furthermore, some studies suggest a role for β-catenin (and Wnt) in synaptic plasticity (Salinas 1999; Salinas and Hall 1999). Additional studies have suggested that β-catenin itself may play an important role for this protein in the function of the brain. Indeed, upregulation of this protein is sufficient to cause the formation of gyri and sulci in the mouse brain, a finding observed only in higher mammals, and is suggestive of an important role in higher mammalian cognitive functions (Chenn and Walsh 2002).

PLC-γ1 Pathway

Phosphorylated Trk receptors also recruit PLC-γ1 (see Figure 1–9). The Trk kinase then phosphorylates and activates PLC-γ1, which acts to hydrolyze phosphatidylinositides to generate DAG and IP_3. IP_3 induces the release of Ca^{2+} stores, increasing levels of cytoplasmic Ca^{2+} and thereby activating many pathways controlled by Ca^{2+}. It has been shown that neurotrophins activate protein kinase C δ, which is required for activation of the ERK cascade and for neurite outgrowth (Patapoutian and Reichardt 2001). As discussed previously, emerging data suggest that the regulation of hippocampal LTP by TrkB receptors is mediated primarily through the PLC-γ cascade (for details, see Minichiello et al. 2002).

Phosphorylation/Dephosphorylation

For many proteins, a change in charge and conformation due to the addition or removal of phosphate groups results in alterations in their intrinsic functional activity. Although proteins are covalently modified in many other ways—for example, by ADP ribosylation, acylation (acetylation, myristoylation), carboxymethylation, and glycosylation—none of these mechanisms appear to be as widespread and readily subject to regulation by physiological stimuli as phosphorylation. Indeed, protein phosphorylation/dephosphorylation represents a pathway of fundamental importance in the chemistry of biological regulation (see Nestler et al. 2001). Virtually all types of extracellular signals are known to produce many of their diverse physiological effects by regulating the state of phosphorylation of specific proteins in the cells that they target.

The phosphate group provides an unwieldy negative charge that often interacts with the catalytic and other regions of enzymes. The addition of a phosphate often results in conformational changes in proteins. In the case of enzymes, this change may increase (more commonly) or decrease the affinity of an enzyme for its substrate. Thus, phosphorylation may result in a change in kinase activity, a change in phosphatase activity, or the marking of a protein for cleavage by proteases. The catalytic activity of an enzyme can be switched on or off, or an ion channel can be opened or closed. For many other proteins, phosphorylation-induced changes in charge and conformation result in alterations in the affinity of the proteins for other molecules. For example, phosphorylation alters the affinity of numerous enzymes for their cofactors and end-product inhibitors, phosphorylation of receptors can alter their affinity for G proteins, and phosphorylation of some nuclear transcription factors alters their DNA-binding properties. Therefore, phosphorylation can produce varied effects on cellular physiology and ultimately can have major behavioral manifestations.

Protein kinases are classified by the residues that they phosphorylate, with the two major classes being serine/threonine kinases and tyrosine kinases. Most phosphorylation (>95%) of proteins occurs on serine residues, a small amount (about 3%–4%) on threonine residues, and very little (0.1%) on tyrosine residues (but, as discussed earlier, the tyrosine kinases can be very important for neurotrophic signaling). In all cases, the kinases catalyze the transfer of the terminal (γ) phosphate group of ATP to the hydroxyl moiety in the respective amino acid residue, a process that requires Mg^{2+}. Within cells, protein kinases often form sequential pathways, whereby one kinase phosphorylates/activates another, which phosphorylates/activates another kinase, and so forth. In this manner, signals can be propagated within cells, allowing ample opportunity (see below) for the signal to be altered by other intracellular signals, often in a cell type–specific manner, allowing for considerable "fine-tuning."

Although clearly playing critical roles in modulating the function of proteins by catalyzing the cleavage of the phosphoester bond, *protein phosphatases* have not been as extensively studied as kinases. In the CNS, phosphatases often function as a molecular "off switch," thereby decreasing the activity of enzymes and the intracellular signaling pathways they control. However, it is clear that protein phosphatases are much more than simple off switches. Thus, in an elegant series of studies, Greengard and associates demonstrated that a major CNS phosphoprotein, known by the acronym DARPP-32 (dopamine and cAMP-regulated phosphoprotein, 32 kDa), brings about many of its long-term neuroplastic effects by regulating the activity of a protein phosphatase (protein phosphatase–1; PP-1) (for a review, see Greengard 2001a). Thus, they demonstrated that the DARPP-32/PP-1 pathway integrates information from a variety of neurotransmitters and produces a coordinated response involving numerous downstream physiological effectors. DARPP-32 phosphorylation by PKA is regulated by the actions of various neurotransmitters, principally dopamine acting at D_1 receptors but also a variety of other neurotransmitters (Greengard 2001b; Nestler et al. 2001). Phospho-DARPP-32, by inhibiting the activity of PP-1, acts in a synergistic manner with different protein kinases (primarily PKA and PKC) to increase the level of phosphorylation of various downstream effector proteins and thereby long-term neuronal adaptations that have also been implicated in the actions of drugs of abuse and antidepressants (Greengard 2001b; Nestler et al. 2001).

While propagation of signals may be very immediate, even short-term phosphorylation of many types of proteins can have long-term effects, resulting in "molecular and cellular memory." Indeed, various forms of learning and memory are known to be regulated, in large part, by phosphorylation events. Short-term memory may involve the phosphorylation of presynaptic or postsynaptic proteins in response to synaptic activity, a process that results in transient facilitation or inhibition of synaptic transmission. Long-term memory may involve phosphorylation of proteins that play a role in the regulation of gene expression, which would result in more permanent modifications of synaptic transmission, potentially via structural brain changes (Malenka and Nicoll 1999). As discussed, long-term potentiation, one of the most extensively studied models of learning and memory, is believed to be initiated through short-term changes in Ca^{2+}-dependent protein phosphorylation and maintained by long-term changes in gene expression. There is also growing appreciation that protein phosphatases play a critical role in the *extinction* of memory. Thus, abundant data now suggest that rather than representing a passive process, "forgetting" is more an *active process of memory erasure* (discussed in Genoux et al. 2002). In an elegant series of behavioral studies using transgenic mice, Genoux et al. (2002) provided strong evidence that PP-1 is involved in forgetting rather than in preventing the encoding of memory. Although the precise mechanisms by which PP-1 brings about these effects remain to be fully elucidated, these investigators postulate that CaMKII and the GluR1 subunit of the AMPA receptor play important roles. These findings may have major implications for the ultimate development of agents that could be used to facilitate the erasure of traumatic memories—for example, in PTSD.

CONCLUSION

In this chapter, we have attempted to provide an overview of some fundamental aspects of neurotransmitters, signal transduction pathways, and second messengers. For most psychiatrists, molecular and cellular biology have not traditionally played a major role in day-to-day clinical practice. However, new insights into the molecular and cellular basis of disease and drug action are being generated at an ever-increasing rate and will ultimately result in a transformation of our understanding and management of diseases. Indeed, the last decade of the twentieth century was truly a remarkable one for biomedical research. The "molecular medicine revolution" has utilized the power of sophisticated cellular and molecular biological methodologies to tackle

many of society's most devastating illnesses. The rate of progress has been exciting indeed, and hundreds of G protein–coupled receptors and dozens of G proteins and effectors have now been identified and characterized at the molecular and cellular levels. These efforts have allowed the study of a variety of human diseases that are caused by abnormalities in cell-to-cell communication; studies of such diseases are offering unique insights into the physiological and pathophysiological functioning of many cellular transmembrane signaling pathways.

Psychiatry, like much of the rest of medicine, has entered a new and exciting age demarcated by the rapid advances and the promise of molecular and cellular biology and neuroimaging. There is a growing appreciation that severe psychiatric disorders arise from abnormalities in cellular plasticity cascades, leading to aberrant information processing in synapses and circuits mediating affective, cognitive, motoric, and neurovegetative functions. Thus, these illnesses can be best conceptualized as genetically influenced disorders of synapses and circuits rather than simply as deficits or excesses in individual neurotransmitters (Carlson et al. 2006). Furthermore, many of these pathways play critical roles not only in synaptic (and therefore behavioral) plasticity but also in long-term atrophic processes. Targeting these cascades in treatment may stabilize the underlying disease process by reducing the frequency and severity of the profound mood cycling that contributes to morbidity and mortality. The role of cellular signaling cascades offers much explanatory power for understanding the complex neurobiology of bipolar illness (Goodwin and Jamison 2007). Signaling cascades regulate the multiple neurotransmitter and neuropeptide systems implicated in psychiatric disorders and are targets for the most effective treatments. The highly integrated monoamine and prominent neuropeptide pathways are known to originate in and project heavily to limbic-related regions, such as the hippocampus, hypothalamus, and brain stem, which are likely associated with neurovegetative symptoms. Abnormalities in cellular signaling cascades that regulate diverse physiological functions likely explain the tremendous medical comorbidity associated with psychiatric disorders.

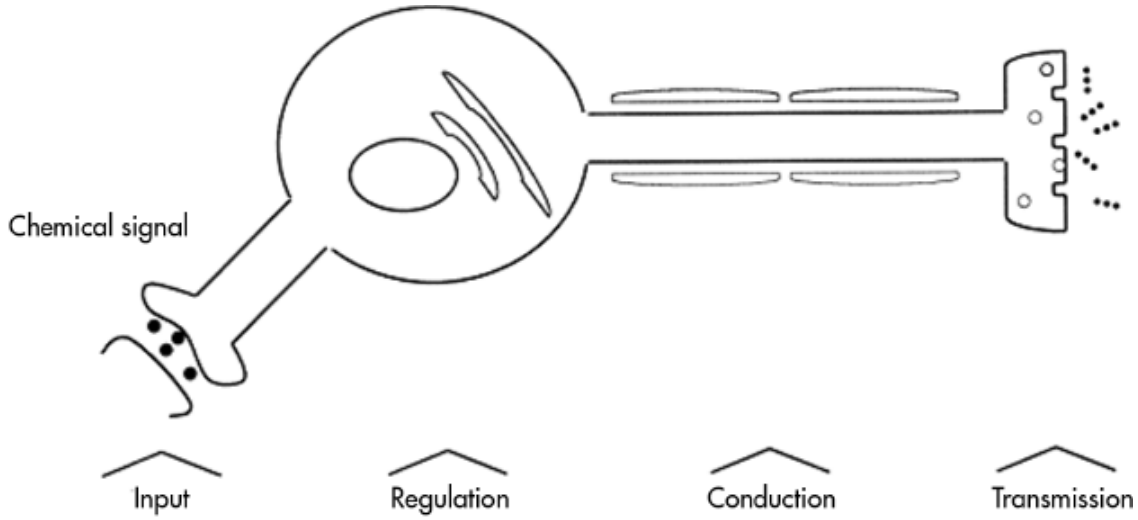
Chapter 2. Basic Principles of Molecular Biology and Genomics

BASIC PRINCIPLES OF MOLECULAR BIOLOGY AND GENOMICS: INTRODUCTION

In June 2000, it was announced that both a corporate effort and a government consortium had succeeded in sequencing all of the human genome. This was followed by the publication of that sequence in February 2001 (Lander et al. 2001; Venter et al. 2001). For anyone involved in biology or medicine, these events represented a revolution in the technical and conceptual approach to both research and therapy.

It seems that humans are far less complex than most scientists had previously thought. Rather than having 100,000–150,000 genes, as was once the belief, humans may have only about 30,000 genes. At this point, not all of those genes have an identified function, and it is becoming clear that many gene products have more than one function. Perhaps more importantly, genes that have been identified in a single cell type may have an entirely different function in other cell types. Some other genes may enjoy a brief and transient expression during the process of embryonic development only to play an entirely different role in the adult. Truly understanding those genes and gene products will revolutionize all of science, and this may be especially true for psychiatry.

Consider that prior to identification of the genome, psychiatric genomics has been limited to studies of chromosomal linkage wherein a putative gene for a disorder could be roughly localized to a given region of a chromosome. The burgeoning understanding of the human genome now occurring has led to a rudimentary understanding of genetic variation among humans. In many humans, a single base or single nucleotide is modified, and it is a combination of knowing the entire genetic code and determining aberrations in individuals with disease that will allow the pinpointing of specific genes associated with psychiatric diseases.



New advances and technology are also furthering our understanding of the genome. Microarrays, which permit one to put several genes on a chip, show the ability of a given cell or tissue to activate given genes. Sometimes, during a disease process, inappropriate genes are activated or inactivated. Identification of these genes also helps to shed light on the disease process and on possible therapy. At the same time that rapid advances are being made in understanding the genome, rapid advances in molecular biology are allowing the manipulation of genes and proteins in individual nerve cells. The development of molecular and cellular models for neuropsychiatric disease has also permitted tremendous advancement in our understanding of both biochemical defects and possible new approaches toward ameliorating those defects.

In this chapter, we present information about genetics, genomics, and the genome and explain modern molecular biology and the investigative methods used in that field. We also discuss pathophysiology, as related to neuropsychiatry and molecular strategy, and introduce findings from studies on the cell biology of the neuron that help us to understand both psychopharmacology and the biology of the brain and mind.

CELL BIOLOGY OF THE NEURON

To appreciate the molecular biology presented in this chapter, it is necessary to describe the components of the neuron that process signals that directly or indirectly modify the aspects of the genome described below. Neurons —specialized cells that function to transmit signals to other neurons, muscles, and secretory cells—contain four basic domains (Figure 2–1), and these domains serve to receive signals, process and integrate signals, conduct impulses, and release transmitter.

FIGURE 2–1. Diagram of a typical neuron.

As described in the text, this neuron is divided into zones for the reception of signals (input = dendrites), integration of signals (regulation = nucleus and soma), conduction of signals (axon), and transmission of signals (axon terminal).

The nucleus resides in the cell body (the signal processing domain) and contains the DNA that codes for the genes expressed by neurons. Activation of a given gene results in the generation of a messenger RNA (mRNA), which is then translated into a protein (see below). Although such events are common to all cells, neural cells are unique in some aspects of molecular signaling. Of importance, the variety of gene expression is far greater in the brain than in any other organ or tissue. Some estimates are that in aggregate, the brain expresses as much as 10 times the number of genes expressed in any other tissue. This does not mean that individual neurons undergo a much greater gene expression. Rather, it suggests an extraordinary heterogeneity among neurons and glia, which allows for a rich regulation when those neurons and glia assemble into the elaborate network of the human brain.

mRNA molecules exported from the nucleus are translated into proteins by ribosomes in the endoplasmic reticulum. Note that most of the protein production occurs in the cell body, although there is also some mRNA in the dendrites (Steward and Wallace 1995). This means that newly made proteins must be transported from that cell body to the axon terminal, a distance as great as 1 m. These proteins are often packaged in vesicles, and specialized "motor" molecules transport packaged proteins down microtubule "tracks" at the cost of adenosine triphosphate (ATP) hydrolysis (Setou et al. 2000).

ESSENTIAL PRINCIPLES OF GENE EXPRESSION

Genes and DNA

The DNA double helix transmits genetic information from generation to generation and is the repository of information required to guide an organism's development and interaction with the environment. The role of DNA in storing and transferring hereditary information depends on the innate properties of its four constituent bases. There are two purine bases, adenine (A) and guanine (G), and two pyrimidine bases, cytosine (C) and thymine (T). Within the DNA double helix, A is complementary to T, and G is complementary to C. Each block of DNA that codes for a single RNA or protein is called a *gene,* and the entire set of genes in a cell, organelle, or virus forms its *genome.* Cells and organelles may contain more than one copy of their genome. There are 46 chromosomes in a typical human cell; when "unraveled," the total DNA of a single cell is approximately 1 m in length. The 46 human chromosomes consist of 22 pairs of autosomes and 2 sex chromosomes, either XX for females or XY for males. Such a large amount of genetic material is effectively packaged into a cell nucleus, which is also the site of DNA replication and transcription. Only a small percentage of chromosomal DNA in the human genome is responsible for encoding the genes that act as a template for RNA strands; there are approximately 20,000–25,000 genes total, of which about 10,000–15,000 genes are expressed in any individual cell.

Among RNA strands, only ribosomal RNA (rRNA), transfer RNA (tRNA), and small nuclear RNA (snRNA) have independent cellular functions. Most cellular RNA, mRNA, serves as a template for protein synthesis. RNA, like DNA, is also composed of four nucleotide building blocks. However, in RNA, the nucleotide uracil (U) takes the

place of thymine (T), and RNA is a flexible single strand that is free to fold into a variety of conformations. Thus, the functional versatility of RNA greatly exceeds that of DNA.

Chromosomal DNA contains both genes and more extensive intergenic regions. Some regions of DNA in genes act as the template for RNA, but some regions are responsible for regulatory functions. The distribution of genes on chromosomes is not uniform: some chromosomal regions, and indeed whole chromosomes, are richly endowed with genes, whereas other regions are more amply supplied with noncoding DNA. Regulation of gene expression conferred by the nucleotide sequence of a DNA molecule is referred to as *cis*-regulation, because the regulatory and transcribed regions occur on the same DNA molecule. *cis*-Regulatory elements that determine the transcription start site of a gene are called *basal* (or *core*) *promoters;* other *cis*-regulatory elements are responsible for tethering different activators and repressor proteins to DNA. There are specific regions of DNA that bind to regulatory proteins. These regulatory proteins may be encoded at any regions in the genome, and because they are not coded by the stretch of DNA to which they bind, they are sometimes called *trans*-acting factors. *Trans*-acting factors that regulate the transcription of DNA are also called *transcription factors.*

DNA Replication

Chromosomal DNA must be replicated to coordinate with cell division. Replication begins at a sequence called the *origin of replication.* It involves the separation of the double helix DNA strands over a short length and the binding of enzymes, including DNA and RNA polymerases. During DNA replication, each existing strand of DNA serves as a template for the synthesis of a new double helix that contains one old strand and one strand that is newly synthesized but complementary. This process is known as *semiconservative replication.* In the process of cell division, each of the 46 double helices is replicated and folded into chromosomes.

Transcription

Only a fraction of all the genes in a genome are expressed in a given cell or at a given time. These genes undergo the process of *transcription,* in which an RNA molecule complementary to one of the gene's DNA strands is synthesized in a 5' to 3' direction, using nucleotide triphosphates. Transcription can be classified into three discrete steps: initiation, mRNA chain elongation, and chain termination. Transcriptional regulation may occur at any step in the process; however, initiation appears to be the primary control point because, in a sense, it is the rate-limiting step. Localization of the transcription start site and regulation of the rate of transcription are essential to initiation. The *cis*- and *trans*-acting factors described above all regulate the initiation of transcription.

Translation

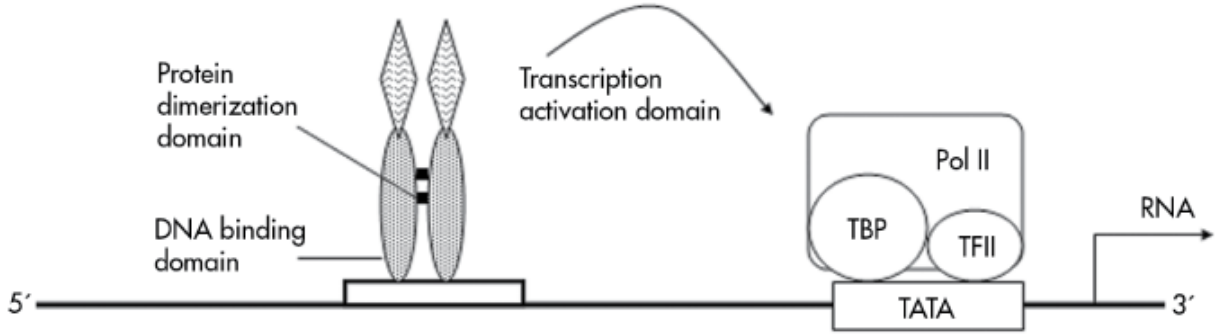
Each mRNA in a cell can code for the primary amino acid sequence of a protein, using a triplet of nucleotides (codon) to represent each of the amino acids. Some amino acids are represented by more than one codon, because there are more triplet codons than there are amino acids. The codons in mRNA do not interact directly with the amino acids they specify. The translation of the individual codons of mRNA into protein depends on the presence of another RNA molecule, tRNA, which has a cloverleaf structure. On the top leaf of the tRNA structure, three nucleotides form a complementary codon (an anticodon) to each mRNA nucleotide triplet. Thus, each mRNA nucleotide triplet can code for a specific amino acid. Each tRNA carries an amino acid corresponding to its anticodon, and when thus "charged," the complex is termed *aminoacyl-tRNA.* Anticodons of aminoacyl-tRNA bind with mRNA codons in ribosomes. Ribosomes, a complex of rRNA and enzymes needed for translation, provide the structure on which tRNA can bind with the codons of mRNA in sequential order.

Initiation of protein synthesis involves the assembly of the components of the translation system. These components include the two ribosomal subunits, the mRNA to be translated, the aminoacyl-tRNA specified by the first codon in the message, guanosine triphosphate (GTP), and initiation factors that facilitate the assembly of this initiation complex. In eukaryotes, there are at least 12 distinct translation initiation factors (Roll-Mecak et al. 2000). After the ribosome recognizes the specific start site on the mRNA sequence, which is always the codon AUG coding for methionine, it slides along the mRNA molecule strand and translates the nucleotide sequence one codon at a time, adding amino acids to the growing end of the polypeptide chain (the elongation process). During elongation, the ribosome moves from the 5'-end to the 3'-end of the mRNA that is being translated. The binding of GTP to the elongation factor tu (EFtu) promotes the binding of aminoacyl-tRNA to the ribosome (Wieden et al. 2002). When the ribosome finds a stop codon (UAA, UGA, or UAG) in the message RNA, the mRNA, the tRNA, and the newly synthesized protein are released from the ribosomes, with the help of release factors that also bind GTP. The translation process is stopped, and a nascent protein exists.

It is noteworthy that initiation, elongation, and release factors undergo a conformational change upon the binding of GTP. In this regard, they are similar to the G proteins (both heterotrimeric G proteins and small "ras-like" G proteins) involved in cellular signaling (Halliday et al. 1984; Kaziro et al. 1991).

REGULATION OF GENE EXPRESSION

Chromatin and DNA Methylation



Biophysics and molecular biology have revealed that chromatin consists of a repetitive nucleoprotein complex, the nucleosome. This particle consists of a histone octamer, with two copies of each of the histones (H2A, H2B, H3, and H4), wrapped by 147 base pairs of DNA. In the octamer, histones H3 and H4 are assembled in a tetramer, which is flanked by two H2A–H2B dimers. A variable length of DNA completes the second turn around the histone octamer and interacts with a fifth histone, H1. H2A, H2B, H3, and H4 are variously modified at their amino- and carboxyl-terminal tails to influence the dynamics of chromatin structure and function (Ballestar and Esteller 2002; Keshet et al. 1986; Kornberg and Lorch 1999; Strahl and Allis 2000). Although chromatin provides structure to chromosomes, it also plays a critical role in transcriptional regulation in eukaryotes because it can repress gene expression by inhibiting the ability of transcription factors to access DNA. In fact, chromatin ensures that genes are inactive until their expression is commanded. In the activation process, cells must attenuate nucleosome-mediated repression of an appropriate subset of genes by means of activator proteins that modify chromatin structure. An activator protein displaces nucleosomes, which permits a complex of proteins (general transcription factors) to bind DNA at a promoter and to recruit RNA polymerase.

Cytosine methylation at CpG dinucleotides is the most common modification of the eukaryotic genome. In vertebrates, methylation occurs globally throughout the genome, with the exception of CpG islands. These are CG-rich regions of DNA that stretch for an average of ~1 kilobase (kb), coincident with the promoters of 60% of human RNA polymerase II–transcribed genes. Methylation of cytosines at CpG represses transcription (Ballestar and Esteller 2002). *Genetic imprinting,* a process by which particular paternal or maternal genes are inactivated throughout a species, is at least partly controlled by DNA methylation. Specific proteins binding to methylated DNA may establish a bridge between chromatin and DNA methylation. They recruit histone deacetylases (HDACs) to activate a methylated promoter, which in turn deacetylates histones, leading to a repressed state (Ballestar and Esteller 2002; Keshet et al. 1986).

RNA Polymerases

There are three distinct classes of RNA polymerase—RNA polymerase I, RNA polymerase II, and RNA polymerase III—in the nucleus of eukaryotic cells, and they are designed to carry out transcription. RNA polymerase I synthesizes large rRNA molecules. RNA polymerase II is mainly used to yield mRNA and, subsequently, proteins. RNA polymerase III produces snRNA, small rRNA, and tRNA molecules. Each class of RNA polymerase recognizes particular types of genes. However, RNA polymerases do not bind to DNA directly. Rather, they are recruited to DNA by other proteins that bind to promoters (Figure 2–2).

FIGURE 2–2. Transcription factors and RNA polymerase II complex.

Typical transcription factors contain DNA-binding domains, protein dimerization domains, and transcription activation domains. Some transcription factors (e.g., cAMP response element–binding protein [CREB]) may be modified by phosphorylation. The transcription activation domain interacts with an RNA polymerase II (Pol II) complex to induce transcription. TATA binding protein (TBP) binds to the TATA box element and associates with general transcription factors (TFII). This gene transcription apparatus recruits Pol II to the appropriate gene.

mRNA is transcribed from DNA by RNA polymerase II with heterogeneous nuclear RNA (hnRNA), an intermediate product. The core promoter recognized by RNA polymerase II is the TATA box (Hogness box), a sequence rich in nucleotides A and T, which is usually located 25–30 bases upstream of the transcription start site. The TATA box determines the start site of transcription and orients the basal transcription complex that binds to DNA and recruits RNA polymerase II to the TATA box; thus, it establishes the 5' to 3' direction in which RNA polymerase II synthesizes RNA. The formation of the basal transcription complex is promoted by a *TATA binding protein* (TBP) that binds to a core promoter, together with multiple TBP-associated factors and other general transcription factors. *Enhancers* are DNA sequences that increase the rate of initiation of transcription by RNA polymerase II through its interaction with transcription factors, which can be located "upstream" or "downstream" of the transcription start site. Enhancer elements are important to cell-specific and stimulus-dependent expression of hnRNA. Some RNA polymerase II species, including those for many genes that are expressed in neurons, lack a TATA box and possess instead an *initiator,* a poorly conserved genetic promoter element.

Transcription Factors

Transcription factors act as the key regulators of gene expression. Sequence-specific transcription factors typically contain physically distinct functional domains (see Figure 2–2). Numerous transcription factors have been found. Some of them translocate to the nucleus to bind their *cis*-regulatory elements in response to activation reaction, such as nuclear factor κB (NF-κB). However, some transcription factors are already bound to their cognate *cis*-regulatory elements in the nucleus under basal conditions and are converted into transcriptional activators by phosphorylation. cAMP (cyclic 3'-5'-adenosine monophosphate) response element–binding protein (CREB), for example, is bound to regions of DNA, called *cAMP response elements* (CREs), before cell stimulation. CREB can promote transcription when it is phosphorylated on a serine residue (ser133), because phosphorylated CREB can interact with a coactivator, CREB-binding protein, which in turn contacts and activates the basal transcription complex. Of interest, CREB-binding protein possesses intrinsic histone acetyltransferase (HAT) activity. The activity of most transcription factors is regulated through second-messenger pathways. CREB can be activated via phosphorylation at ser133 by second messengers, such as cAMP, Ca^{++}, and growth factors (Figure 2–3).

Signal cascades are activated by external stimuli, such as hormones or neurotransmitters and growth factors. *Arrows* indicate the interaction between pathways. AC = adenylyl cyclase; C = catalytic subunits of PKA; Ca^{++} = calcium; CaMK IV = calmodulin-dependent kinase IV; cAMP = cyclic 3'-5'-adenosine monophosphate; CBP = CREB-binding protein; Epac = exchange protein activated by cAMP; ERK = extracellular-regulated kinase; $G\alpha_s$ = α subunit of the stimulatory G protein; P = phosphorylation; PKA = cAMP–dependent protein kinase; R = regulatory subunits of PKA; Rap and Ras = small GTPases (small proteins that bind to guanosine triphosphate [GTP]); RSK2 = ribosomal S6 kinase 2.

CREB is a molecule that is widely implicated in learning and memory in many species. Mice expressing mutant CREB isoforms show impaired memory, but this is dependent on the genetic background of the mice (Graves et al. 2002). CREB-binding protein (CBP) is a transcriptional coactivator with CREB. A partial-knockout mouse model, in which CBP activity is lost, exhibits learning deficiencies (Oike et al. 1999). Further, Rubinstein-Taybi syndrome (RTS) is an autosomal-dominant dysmorphic syndrome that results in severe impairment of learning and memory. The RTS gene has been mapped to chromosome 16 and identified as CBP. The loss of function of CBP is likely one important contributing factor to the learning and memory defects seen in RTS (Murata et al. 2001; Oike et al. 1999; Petrij et al. 1995).

Posttranscriptional Modification of RNA

The mRNA of prokaryotes can be used without any modification to direct protein synthesis, but posttranscription processing of mRNA is needed in eukaryotes. The DNA sequences that code for mRNA (exons) are frequently interrupted by intervening DNA sequences (introns). When a protein-coding gene is first transcribed, the hnRNA contains both exons and introns. Before the transcript exits the nucleus, its introns are removed and its exons are spliced to form mature mRNA (Figure 2–4). The hnRNA that is synthesized by RNA polymerase has a 7-methyl-guanosine "cap" added at the 5' end. The cap appears to facilitate the initiation of translation and to help stabilize the mRNA. In addition, most eukaryotic mRNA has a chain of 40–200 adenine nucleotides attached to the 3' end of the mRNA. The poly (A) tail is not transcribed from DNA; rather, it is added after transcription by the nuclear enzyme poly (A) polymerase. The poly (A) tail may help stabilize the mRNA and facilitate mRNA exit from the nucleus. After the mRNA enters the cytoplasm, the poly (A) tail is gradually shortened.

The horizontal black line between exons indicates an intron. The region before the first exon is the 5' regulatory region of the gene, such as a TATA box. There also are *cis*-regulatory elements in introns and downstream of the last exon. The heterogeneous nuclear RNA (hnRNA), containing both exons and introns, is spliced to form mRNA. mRNAs are then exported from the nucleus to the cytoplasm, where they will direct the synthesis of distinct proteins.

RNA Editing

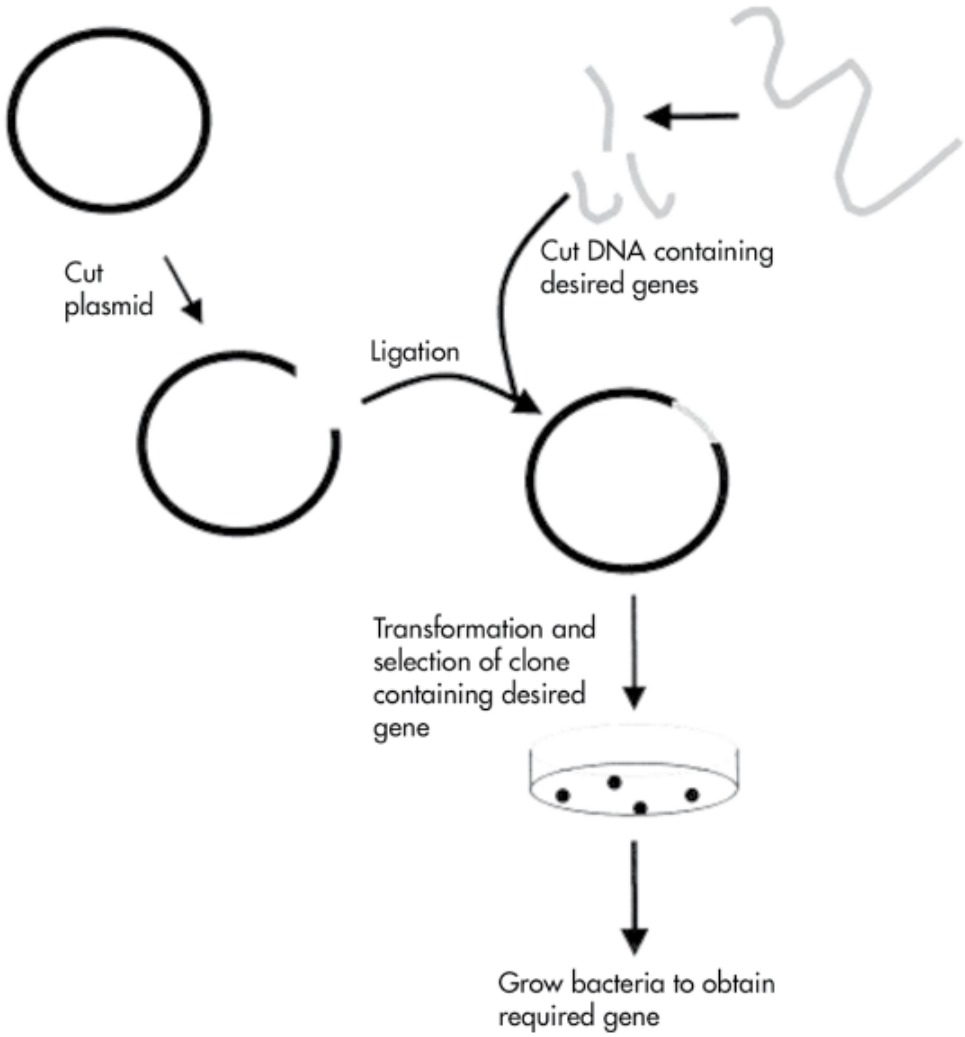
RNA editing has been detected in eukaryotes ranging from single-celled protozoa to mammals and plants and is now recognized as a type of RNA process (posttranscriptional modification of RNA) that differs from the established processes of RNA splicing, 5' end formation, and 3' endonucleolytic cleavage and polyadenylation (DeCerbo and Carmichael 2005; Kable et al. 1997). The conversion of adenosine to inosine was observed first in yeast tRNA (Grosjean et al. 1996) but has since been detected in viral RNA transcripts and mammalian cellular RNA (Bass 1997; Simpson and Emeson 1996). The inosine residues generated from adenosines can alter the coding information of the transcripts, as inosine is synonymous for guanosine during transcript translation. For example, upon A-to-I editing, the CAC codon for histamine is transformed to CIC, coding for arginine. RNA editing can have dramatic consequences for the expression of genetic information, and in a number of cases it has been shown to lead to the expression of proteins not only with altered amino acid sequences from those predicted from the DNA sequence but also with altered biological functions (Bass 2002; Burns et al. 1997).

The enzymes for RNA editing are referred to as *adenosine deaminases that act on RNA* (ADARs). ADARs target RNA that is double-stranded and convert adenosines to inosines by catalyzing a hydrolytic deamination at the adenine base (Bass 2002). Mammals have several ADARs, of which two (ADAR1 andADAR2) are expressed in most tissues of the body (Seeburg and Hartner 2003). RNA editing may also catalyze the conversion of one or a few adenosines in a transcript to inosines (Maas et al. 1997; Stuart and Panigrahi 2002). On the other hand, RNA editing can convert numerous adenosines to inosines in RNA. This type of editing is thought to be the result of aberrant production of dsRNA (DeCerbo and Carmichael 2005) and has been suggested to lead to RNA degradation (Scadden and Smith 2001), nuclear retention (Zhang and Carmichael 2001), or even gene silencing (Wang et al. 2005).

The 5-HT_{2C} receptor is a G protein–coupled receptor that is well known to have variants generated by A-to-I editing (Burns et al. 1997). 5-HT_{2C} receptor transcripts can be edited at up to five sites, potentially generating 24 different receptor versions, and hence a diverse receptor population. The RNA-edited 5-HT_{2C} receptor affects ligand affinity and the efficacy of G protein coupling (Berg et al. 2001; Wang et al. 2000; Yang et al. 2004). The unedited form of the 5-HT_{2C} receptor has the highest affinity to serotonin and exhibits constitutive activity independent of serotonin levels. When RNA is edited, the basal activity of the 5-HT_{2C} receptor is suppressed, and agonist potency and efficacy are modified.

Modification of the Nascent Polypeptide Chain

The posttranslational modifications described above occur after translation is initiated. They may include removal of part of the translated sequence or the covalent addition of one or more chemical groups that are required for protein activity. Some of these modifications, such as glycosylation or prenylation, represent an obligatory step in the synthesis of the "finished" protein product. In addition, many proteins may be activated or inactivated by the covalent attachment of a variety of chemical groups. Phosphorylation, glycosylation, hydroxylation, and prenylation are common types of covalent alterations in posttranslational modifications. A number of different enzymes coordinate these processes, and they represent a major portion of the events of cellular signaling.



APPROACHES TO DETERMINING AND MANIPULATING GENE EXPRESSION

Changes in gene expression within the central nervous system (CNS) have profound effects on all other aspects of the organism. Changes in gene expression are causally associated not only with the development of the CNS but also with the complex phenomena of brain function, such as memory formation, learning, cognition, and affective state. Changes in gene expression likely underlie the pathogenesis of many sporadic or inherited CNS-related disorders, such as Alzheimer's disease, Huntington's disease, depression, and schizophrenia. Thus, insight into and characterization of gene expression profiles are necessary steps for understanding how the brain functions at the molecular level and how malfunction will result in disease. Molecular biological and genomic technologies such as gene mapping and cloning, DNA libraries, gene transfection and expression, and gene knockout and gene targeting have provided numerous benefits to neuropsychopharmacology. Genomic methods applied to pedigree and population samples of patients with psychiatric disorders may soon make it possible to identify genes contributing to the etiology and pathogenesis of these diseases and to provide a potential basis for new therapies.

Cloning of DNA

The cloning of DNA confers the ability to replicate and amplify individual pieces of genes. Cloning can be performed with genomic DNA or complementary DNA (cDNA). cDNA is synthesized artificially from mRNA in vitro with the aid of *reverse transcriptase.* Cloned genomic DNA may contain any stretch of DNA, either introns or exons, whereas cloned cDNA consists only of exons. For cloning (see Figure 2–5 for outline of the process), the desired pieces of DNA (often called "inserts") are connected with the DNA of genetically engineered vectors or plasmids, and the vectors are introduced into hosts, such as bacteria or mammalian cells. A DNA library is a collection of cloned restriction fragments of the DNA of an organism that consists of random pieces of genomic DNA (i.e., genomic library) or cDNA (i.e., cDNA library). Complete cDNA libraries contain all of the mRNA molecules expressed in a certain tissue. Sometimes cDNA libraries can be made from a specific tissue in a distinct circumstance. For example, a cDNA library could be made from cerebral cortex in rats undergoing transient forebrain ischemia (Abe et al. 1993).

See text for details.

The cloning of disease-related genes is an important step toward insight into the pathogenesis of diseases and development of new drugs against these diseases. If a protein is suspected of involvement in pathogenesis, a nucleic acid sequence can be deduced from the partial amino acid sequence. cDNA libraries are screened with the partial sequence in order to fish out a complete clone of interest. The isolated cDNA molecules are used to infect bacteria, which amplify the cloned cDNA. Bacteria expressing these cDNA molecules will often make the protein of interest, which can be detected with antibody. A variation on the above technique uses antibodies against the purified proteins to screen a DNA library transfected into bacteriophages. The bacteriophages containing the "right" cDNA can be retrieved, and the sequence of cDNA can be analyzed.

Polymerase Chain Reaction

Polymerase chain reaction **(PCR) is a rapid procedure for in vitro enzymatic amplification of specific segments of DNA. Amplification of the genes of interest occurs by selecting and synthesizing "primers"—stretches of DNA that span the region of interest to be "filled in"—and by heating DNA to make it single stranded, allowing polymerase and primers to bind. The polymerase then reads the "blank" stretch of DNA between the primers and synthesizes DNA corresponding to the region of interest. This is usually done in "thermal cyclers" that heat the DNA at regular intervals and allow "cycles" of PCR to amplify the genes repetitively. To avoid continual addition of polymerase, the DNA polymerase used is often from bacteria that inhabit hot springs or hot ocean vents. This polymerase is not denatured by heating and can therefore support several cycles of PCR.**

A variation on PCR is reverse transcriptase PCR (or RT-PCR), in which the RNA is the template. Reverse

transcriptase (the "RT" of RT-PCR) is employed to synthesize cDNA from the RNA. Enzymatic amplification of this cDNA is then accomplished with PCR.

Real-time PCR is based on the method of RT-PCR, following the reverse transcription of RNA into cDNA. Real-time PCR requires suitable detection chemistries to report the presence of PCR products, as well as an instrument to monitor the amplification in real time through recording of the change in fluorescence (Wittwer et al. 1997). Generally, chemistries in PCR consist of fluorescent probes. Several probes exist, including DNA-binding dyes like EtBr or SYBR green I, hydrolysis probes (5'-nuclease probes), and hybridization probes (Valasek and Repa 2005). Each type of probe has its own unique characteristics, but the strategy for each is to link a change in fluorescence to amplification of DNA (Kubista et al. 2006; Lind et al. 2006). The instrumentation to detect the production of PCR must be able to input energy for excitation of fluorescent chemistries at the desired wavelength and simultaneously detect a particular emission wavelength. Many instrument platforms are available for real-time PCR. The major differences among them are the excitation and emission wavelengths that are available, speed, and the number of reactions that can be run in parallel (Kubista 2004).

Positional Cloning

Disease genes can sometimes be isolated with the aid of *positional cloning,* a process also known as *reverse genetics* (Collins 1995). Positional cloning is the process used to identify a disease gene, based only on knowledge of its chromosomal location, without any knowledge of the biological function of the gene. Positional cloning requires a genetic map of unique DNA segments or genes (genetic markers), with known chromosomal location, that exist in several alternative forms (alleles). These allelic variations (polymorphisms) allow comparisons of the wild type as the "diseased" genotype.

Linkage analysis is a method of localizing one or more genes influencing a trait to specific chromosomal regions. This is performed by examining the cosegregation of the phenotype of interest with genetic markers. Relatives who are phenotypically alike will share common alleles at markers surrounding the genes influencing the phenotype, whereas other relatives (i.e., those who are phenotypically dissimilar) will not carry these alleles. To carry out linkage analyses, investigators need, minimally, a set of families in which phenotyped individuals have known relationships to one another and the genotypes of these individuals, including one or more genetic markers.

Once the chromosomal location of the disease gene has been ascertained, the area of chromosomal DNA can be cloned. Until recently, the process of positional cloning involved laborious efforts to build a physical map and to sequence the region. (The sequencing of the human genome has obviated this step.) Physical maps can be produced by isolating and linking together yeast and/or bacterial artificial chromosomes containing segments of human DNA from the region. These fragments are then sequenced and ordered, and from these data, the genomic DNA sequence for the region of the candidate gene region is determined.

Differential Display

The technique of differential display is designed to determine the complement of genes being expressed (mRNAs) by a tissue or an organ at a given point in time. The establishment of differential display is dependent on the random amplification and subsequent size separation of cDNA molecules (Liang et al. 1992). With RT-PCR amplification with specific oligo-T primers (one- or two-base anchored oligo-dT primers, such as oligo-T-XC, oligo-T-XG, oligo-T-XT, and oligo-T-XA; X = G/A/C), four separate cDNA synthesis reactions are performed. These cDNA synthesis reactions form the four pools of cDNA for one original mRNA population. The resulting cDNA molecules from each RT-PCR reaction are amplified, using the same primer of the reverse transcription step plus randomly chosen primers. Because the randomly chosen primers will anneal at various locations upstream of the oligo-T site, many individual cDNA fragments of different sizes are amplified in each PCR reaction. cDNA fragments derived from different original mRNA populations are sized and then separated on parallel gels to analyze the presence of unique bands. The differentially expressed cDNA fragments can be excised from gels, cloned, and further characterized by a variety of technologies based on different purposes, such as in situ hybridization, sequences, and Northern blot analysis.

Differential display is a useful tool in identifying region-specific mRNA transcripts in brain. The molecular markers for these regions can be found by screening for gene expression in specific brain regions or nuclei (Mizushima et al. 2000; Tochitani et al. 2001). In addition, under different stimulation or behavioral conditions, the changes in gene expression can be explored by differential display (Hong et al. 2002; Q. R. Liu et al. 2002; Mello et al. 1997; Tsai et al. 2002). This technique has even been adapted to indicate the RNA expression profile of an individual

neuron (Eberwine et al. 1992). Many genes related to ischemia or Alzheimer's disease in the CNS were also isolated by means of differential display (Doyu et al. 2001; Imaizumi et al. 1997; Tanaka et al. 2002). Genes that are activated in response to chronic drug treatment (e.g., opiates or antidepressants) can also be identified this way. Furthermore, as described later in this chapter (see "Microarray Technology"), streamlined technologies (gene arrays) are now available for this purpose.

Gene Delivery Into Mammalian Cells

The introduction of recombinant DNA (including desired genes) into cells is becoming an increasingly important strategy for understanding certain gene functions in neurons or glia. These advances in gene function studies have benefited the diagnosis of, and therapy for, a variety of disorders that affect the CNS. The delivery of desired genes into cells may also provide the technological base for insight into molecular mechanisms of brain function and, ultimately, for gene therapy in the CNS.

Vectors and Delivery

For gene transfer, it is necessary to incorporate the desired cDNA into various vectors, such as appropriate plasmids or replication-deficient viruses. Vectors used for transfection generally possess two essentially independent functions: 1) carrying genes to the target cell and 2) expressing the genes properly in the target cell. There are currently many commercial vectors with different features from which to choose, and the choice is dependent on the purpose of the experiments and on the characterizations of exogenous desired genes. In one form of transfection, *stable transfection,* cells expressing the gene of interest can be actively selected by a marker (e.g., neomycin resistance genes, *Neo*), and the cDNA or other type of foreign DNA is stably integrated into the DNA of a chromosome. In *transient transfection,* however, cells express the gene of interest for a few days. Cells for hosting the foreign DNA can be either established cell lines or primary cultured neuronal cells. The desired cDNA delivered into cells may be native genes, fragments of the genes, mutant genes, or chimeric genes.

The main barrier to the delivery of DNA into cells is getting the foreign DNA through the cellular membrane. Over the past decades, various methods have been developed to convey the foreign DNA molecules into mammalian cells. These include chemical or physical techniques, such as calcium phosphate coprecipitation of DNA, liposome fusion, electroporation, microinjection, ballistic injection, and viral infection. At present, methods dependent on incorporation of DNA into cationic liposomes (e.g., lipofectin) are used most widely. These methods of transfection are accessible to both cell lines and cultured primary neuronal cells. The ratio of DNA to liposomal suspension, cell density, and time duration of exposure to the DNA–liposomal complex must be optimized for each cell type in culture.

Viral Vectors

Over the past few years, several viral vectors with low toxicity, high infection rate, and persistent expression have extended the methodology of delivery of genes to mammalian cells. These viruses include DNA viruses, such as adenoviruses and adeno-associated viruses, herpes simplex viruses, and RNA retroviruses. Recently, as a result of advances in genetic manipulation, adenoviruses and adeno-associated viruses have been more widely applied to gene transfer. The advantages of adenoviruses are 1) the ability to carry large sequences of foreign DNA, 2) the ability to infect a broad range of cell types, and 3) an almost 100% expression of the foreign gene in cells.

Human adenovirus is a large DNA virus (36 kb of DNA) composed of early genes (from *E1* to *E4*) and later genes (*L1* to *L5*). Wild-type adenovirus cannot be applied to gene transfer, because it causes a lytic infection. Thus, recombinant adenoviruses with defects of some essential viral genes are used for gene delivery. These recently developed adenoviral expression systems are safe; such systems have the capacity for large DNA inserts and allow for relatively simple adenoviral production (Harding et al. 1997; He et al. 1998).

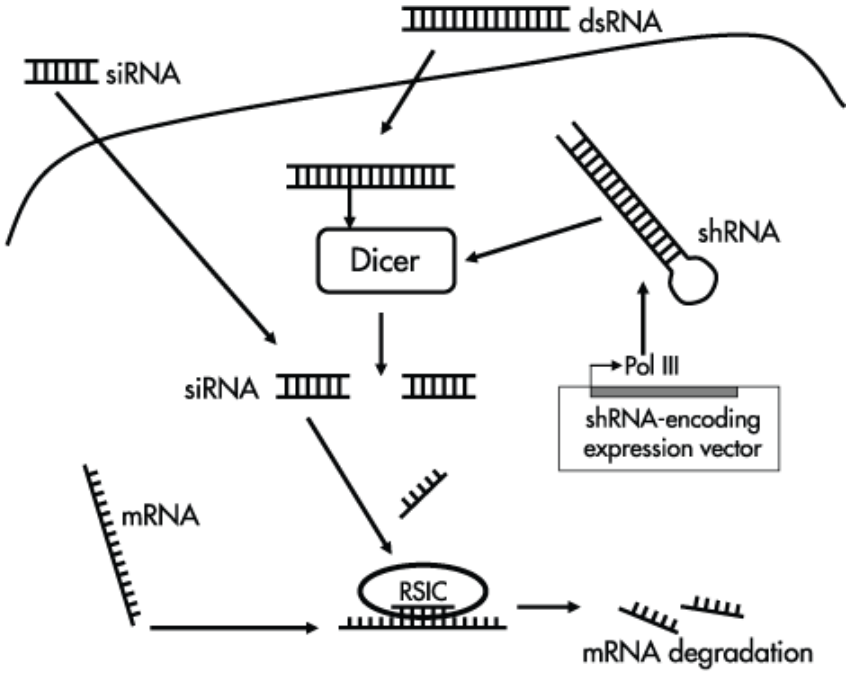
The process of gene transfer into cells (cell lines and primary cells) via recombinant adenoviruses is simple, but the optimal viral titer, the time of exposure to virus, and the multiplicity of infection should be optimized for each cell type. Cell lines and a variety of primary neuronal cells have been infected by adenoviruses (Barkats et al. 1996; Chen and Lambert 2000; Hughes et al. 2002; Koshimizu et al. 2002; Slack et al. 1996). In addition, recombinant adenoviruses containing the desired genes can be delivered to neurons in vivo via intracerebral injection into particular brain areas (Bemelmans et al. 1999; Benraiss et al. 2001; Berry et al. 2001; Neve 1993).

Identification of Ectopic Gene Expression

After delivery of the desired genes into cells, identification of their proper expression is necessary. The general

strategies for identification (Chalfie et al. 1994; Kohara et al. 2001; Yu and Rasenick 2002; Yu et al. 2002b) include

1. The measurement of some functional changes elicited by gene expression in targeted cells. If an enzyme is expressed, this would involve measuring the activity of that enzyme.
2. The detection of the proteins coded by the desired genes by techniques relying on antibodies, such as western blot, immunoprecipitation, and immunocytochemistry. Expression of the desired genes tagged with some epitopes, such as HA, GST, and His-tag, can also be determined with antibodies directed against these epitopes.
3. The use of green fluorescent protein (GFP) as an indicator. GFP, a protein from the jellyfish *Aequorea victoria,* can be either cotransfected with the desired genes or fused with the desired genes before incorporation into cells. The fluorescence from GFP is easy to detect using fluorescent microscopy, and this allows the monitoring of gene expression in living cells. Furthermore, if GFP is fused with the gene of interest, its fluorescence provides a useful tool for studying the function and cellular localization of proteins coded by the genes of interest.



At this point, several different "colors" have been developed through mutation of the initial GFP gene (Shaner et al. 2005). Depending on the wavelengths of excitation, they can be used to localize multiple protein species, or fluorescence resonance energy transfer (FRET) can be used to demonstrate that two target proteins are in close (<10 nm) proximity. FRET uses two fluors with little spectral overlap and depends on the emission of one of the fluors exciting the other.

INHIBITION OF CELLULAR GENE EXPRESSION

RNA Interference

The previous edition of this textbook (2004) mentioned RNA interference as a new technique with great potential for simple manipulation of gene expression. In September 2006, Andrew Z. Fire and Craig C. Mello were awarded a Nobel Prize for this versatile discovery. RNA interference (RNAi) is believed to be a biologically conserved function in a wide range of eukaryotic species. It may play a role in protection against double-stranded RNA viruses (Sijen et al. 2001) and genome-invading transposable elements (Provost et al. 2002; Volpe et al. 2002). Triggered by dsRNA, RNAi identifies and destroys the mRNA that shares homology with the dsRNA. Thus, the expression of a particular gene can be suppressed by introducing dsRNA whose antisense strand sequence matches the mRNA sequence. Fire et al. (1998) first described RNAi in the nematode *Caenorhabditis elegans* as sequence-specific gene silencing in response to double-stranded RNA. The mechanism of RNAi is partly understood, and key proteins involved in the pathway have been identified. In brief, the basic process of RNAi involves the following steps. In a first initiation step, Dicer, an enzyme of the RNase III family, initiates ATP-dependent fragmentation of long dsRNA into 21- to 25-nucleotide double-stranded fragments, termed *small interfering RNAs* (siRNAs). These siRNAs are specifically characterized by overhanging 3' ends of two nucleotides and phosphorylated 5' ends. The siRNA duplexes bind with Dicer, which facilitates the formation of an siRNA/multiprotein complex called *RISC loading complex* (RLC). The siRNA duplex in RLC then unwinds (which requires the protein Ago2) to form an active *RNA-induced silencing complex* (RISC) that contains a single-stranded RNA (called the *guide strand*). The RISC recognizes the target RNA through Watson–Crick base pairing with the guide strand and cleaves the target RNA. Finally, the RISC releases its cleaved product and goes on to catalyze a new cycle of target recognition and cleavage (Figure 2–6) (Tomari and Zamore 2005; Xia et al. 2005).

FIGURE 2–6. Schematic of the mechanism of RNA interference (RNAi) posttranscriptional knockdown of a gene product.

The procedure starts with introduction (transfection, electroporation, or injection) of double-stranded RNA (dsRNA) or small interfering RNA (siRNA) into cells, or expression of small hairpin RNA (shRNA) in cells with vectors encoding shRNAs. The cellular ribonuclease (RNase) Dicer recognizes the long dsRNA molecules and shRNA. Subsequently the dsRNA is cleaved, resulting in 21-nt RNA duplexes, the siRNAs. These siRNA molecules are then incorporated into the RNA-induced silencing complex (RISC) multiprotein complex, where they are unwound by an adenosine triphosphate (ATP)–dependent process, transforming the complex into an active state. Activated RISC uses one strand of the RNA as a bait to bind homologous RNA molecules. The target RNA is cleaved and degraded, resulting in gene silencing.

RNAi Knockdown of Gene Expression

Knockdown of gene expression is accomplished by designing siRNA sequences that target the coding and noncoding regions of the candidate mRNAs with perfect complementarity. In mammalian cells, administration of siRNAs is effective in short-term investigations. Introduction of siRNA into cells is accomplished by transfection or electroporation of either the specific siRNA itself or small hairpin RNA (shRNA) in which the hair loop is rapidly cleaved to produce siRNA. Most of the proposed applications of RNAi incorporate 21-nt siRNA duplexes with 2-nt 3' overhangs, which after chemical synthesis allow large-scale and uniform production of siRNA molecules that are also amenable to stabilizing chemical modifications. Several commercial entities involved in the manufacturing of siRNAs provide effective design algorithms online, which are based on a combination of mRNA target sequence and secondary structures. In some siRNA–target combinations, the use of longer dsRNAs can increase the potency of RNAi (Kim et al. 2005; Siolas et al. 2005).

For stable longer-term suppression, a gene construct coding for the shRNA with a Pol III or a Pol II promoter can be applied (Brummelkamp et al. 2002; Y. Shi 2003; Yu et al. 2002a). RNA Pol II and III promoters are used to drive expression of shRNA constructs (Amarzguioui et al. 2005), depending on the type of expression required. Pol III promoters drive high levels of constitutive shRNA expression, and their transcription initiation points and termination signals are well defined. Pol II promoter–driven shRNAs can be expressed tissue-specifically (Zeng et al. 2002). Expressed shRNAs are efficiently incorporated into RISC, leading to a more potent inhibition of target gene expression. Generally, viral vectors such as adenovirus, lentivirus, or adeno-associated virus can carry the inhibitory construct into cells to achieve adequate expression for knockdown (Kim and Rossi 2007).

RNAi Applications

RNAi is a straightforward method for inducing sequence-specific silencing of one or more genes of interest with the introduction of siRNAs. It has been a powerful tool to investigate gene function. Studies using RNAi have been performed in neuronal cells to examine the functional roles of individual genes in developing growth cones and

neurite outgrowth (Eriksson et al. 2007; Hengst et al. 2006; J. Liu et al. 2007; Schmitz et al. 2007; Yanaka et al. 2007), ion channels (Geng et al. 2004; Lauver et al. 2006; Tahiliani et al. 2007), apoptosis (Yano et al. 2007; Zhang et al. 2007), and a variety of signaling pathways (Meuer et al. 2007; Sanada and Tsai 2005; G. X. Shi et al. 2006; Yamada et al. 2005). Furthermore, RNAi is now being used for the knockdown of gene expression in animals. It appears to apply in virtually all mammalian species, as exemplified by its capability for silencing genes in mice, rats, and goats (Peng et al. 2006; Zhou et al. 2007). Inducible RNAi based on the Cre-loxP system has also been developed in transgenic mice, enabling the investigator to control gene silencing spatially and temporally (Chang et al. 2004; Coumoul et al. 2005; Xia et al. 2006). Thus, it is possible to rapidly establish human genetic diseases as a whole-animal model without the difficulty and expense of embryonic stem cell and gene targeting.

RNAi can knock down specific genes, making it evident that RNAi may be used to disrupt the expression of disease-associated genes for therapeutic purposes. Recent findings have highlighted the possibility of RNAi as a potential therapeutic approach to many human diseases, although a number of challenges need to be addressed, such as the safety concerns and effective delivery of RNAi therapy. RNAi-based therapies for age-related macular degeneration (AMD) and respiratory syncytial virus (RSV) have already reached clinical trials. Moreover, therapies based on RNAi are also in preclinical development for other viral diseases (Rossi 2006), neurodegenerative disorders (Raoul et al. 2006; Xia et al. 2005), and cancers (Pai et al. 2006).

RNAi has become a frequently used tool in a wide range of biomedical research. It has provided a convenient method to study gene function via application of RNAi to cell lines, cultures, and embryonic stem cells. It is anticipated that new uses for this tool will continue to proliferate.

Antisense Oligonucleotides

Antisense oligonucleotides (AOs) are short sequences of nucleotide with about 20 bases that are complementary to some regions of the specific mRNA sequence of interest. When cells take up the short DNA molecules, synthesis of the protein from the specific mRNA is inhibited. The mechanism by which AO blocks the specific protein production remains unclear. Interfering with the selected mRNA stability or its translation may be one potential mechanism (Phillips et al. 1996). Because of specificity, effectiveness, and reversibility, cell-based antisense experiments have proven useful in studying gene and protein function.

PROTEOMIC TECHNIQUES FOR ALTERING CELLULAR FUNCTION

Not all manipulations of gene products are made at the gene level. It is possible to modify cell function by interfering directly with gene products (i.e., the proteomic strategy). One mechanism for such manipulation involves adding peptides that correspond to the active regions of proteins. These peptides bind to the molecular targets of those proteins within the cell and block the downstream effects. Sometimes these peptides can mimic the effect of the larger peptide. For example, a peptide corresponding to the carboxyl-terminal region of a G protein (which interacts with G protein–coupled receptors) was used to block the interaction between receptors and G proteins while "mimicking" the G protein to shift the receptor into a "high affinity" agonist-binding state (Rasenick et al. 1994). Although this strategy usually involves adding peptides to cells made permeable with a detergent or with electric current, it is also possible to incorporate DNA plasmids encoding peptides into cells (Gilchrist et al. 1999).

Another proteomic strategy for manipulating cellular processes involves expression of "dominant-negative" proteins that are generated in sufficient amount to block the activity of the native protein in the cell. Usually this strategy involves the construction of a mutant protein that is similar to the protein of interest but deficient at some active site. This inactive mutant protein, expressed in considerable excess over the native protein, competes with the native protein for target sites and inhibits its activity (Osawa and Johnson 1991).

Proteomics and Beyond

Shotgun proteomics takes its name from shotgun DNA sequencing, in which long DNA sequences are disassembled into shorter, easily readable components and reassembled. Shotgun proteomics works in much the same way as the proteome of a cell is digested, subjected to analysis on mass spectrometry, and "reassembled" into proteins identified through a sophisticated bioinformatic analysis of the protein "fingerprint." At first glance, such an approach might seem problematic, as a tripeptide would have the same mass regardless of the order of the amino acids; however, ionization of the peptide reveals the order of the amino acids. It is the computational algorithms that allow this identification. A recent review explains this in language that any biologist (or psychiatrist) can understand (Marcotte 2007).

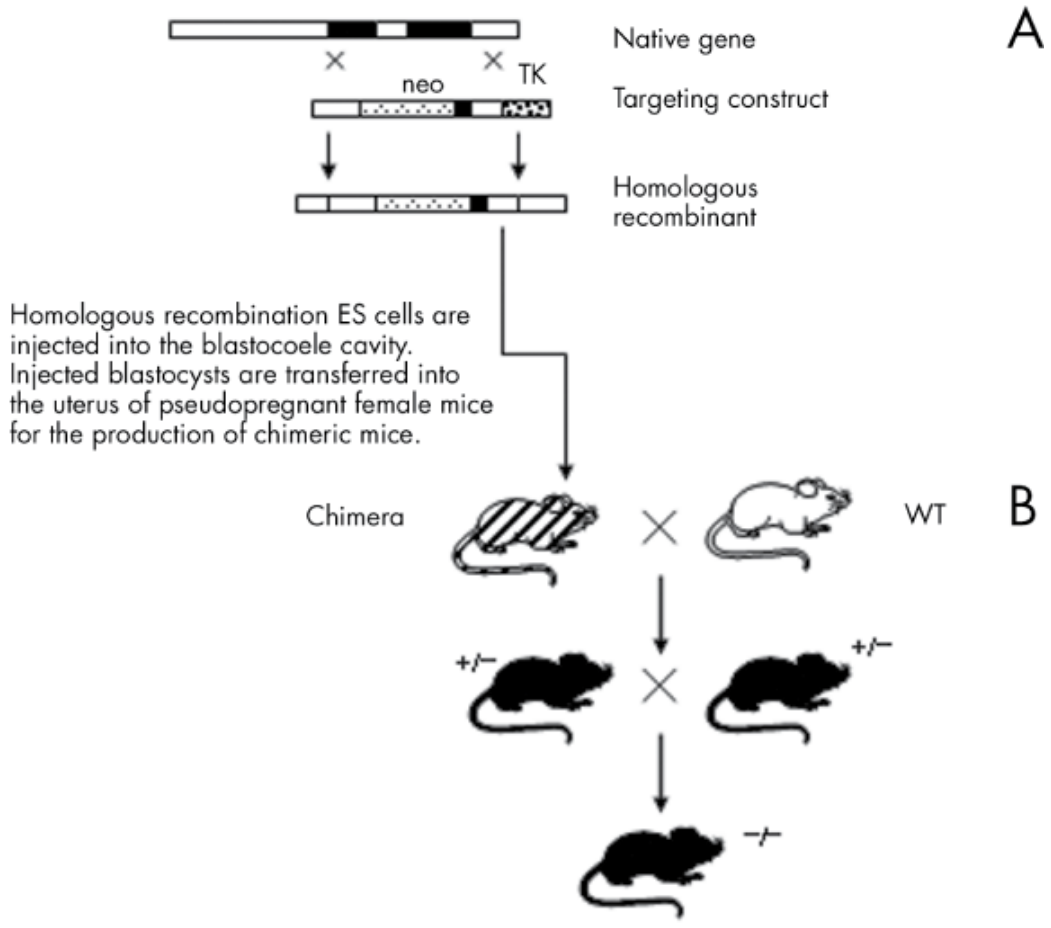
Analysis of the proteome has the potential to yield much more information than simply the identity of the proteins being expressed in a given cell at a given time. Drugs that mimic, antagonize, or alter metabolism of neurotransmitters and neuromodulators comprise the vast majority of the current psychiatric armamentarium. These drugs, often used chronically, have been shown to have long-term effects, altering second-messenger systems. These second messengers (e.g., cAMP, inositol-1,4,5-triphosphate [IP_3], cyclic guanosine monophosphate [cGMP]) activate or inhibit enzymes that modify proteins covalently. Phosphorylation, prenylation, and glycosylation are examples of these modifications, all of which can be determined in mass spectroscopic proteomic analysis.

In addition to—and, in part, due to—the modifications discussed above, molecules involved in neurotransmitter response and responsiveness move among cellular compartments in response to neurotransmitters, neuromodulators, and drugs that affect these. A simple example might be the agonist-induced depalmitoylation of the α subunit of the stimulatory G protein ($G_s\alpha$) that results in its translocation from the plasma membrane (Wedegaertner and Bourne 1994; Yu and Rasenick 2002). We have demonstrated that this translocation is due to collection of G proteins in lipid rafts structures that either amplify or attenuate signaling (Allen et al. 2005, 2007). A catalog of these protein shifts during disease or response to drug can be easily assembled.

As noted above, G protein–coupled receptors comprise targets for a major component of drugs used in psychiatry. Curiously, many of these drugs were thought to have a single site of action until a screening/informatics approach was applied to them. Receptoromics allows screening of compounds for their agonist or antagonist effects on receptors measured through batteries of cells selectively expressing a single species of G protein–coupled receptor (or other receptor or transporter). Results from these studies have been both informative and surprising (Strachan et al. 2006). For example, atypical antipsychotics have been selected for their antagonist properties at the $5\text{-}HT_{2A}$ receptor. Some of these drugs, such as olanzapine, have been associated with excessive weight gain, and this appears to be due to interaction with H_1 receptors—not related to the therapeutic profile of the drug. Other effective antipsychotic drugs may owe their efficacy to actions at a panel of receptors that, when combined, contribute to a therapeutic whole. The ability to screen libraries of compounds against a large number of receptor targets makes design and identification of new drugs an exciting possibility.

TRANSGENIC AND GENE-TARGETING TECHNIQUES

Over the past two decades, progress in the development of molecular genetic methods has enabled the manipulation of genes in intact organisms, such as mice. The technologies have provided a powerful and useful tool that allows the study of gene function and promotes understanding of the molecular mechanisms of disorders of the brain and mind. The mouse genome is by far the most accessible mammalian genome for manipulation. Many successful procedures for introducing new genes, expressing elevated levels of genes, and eliminating or altering the function of identified target genes have been reported. Many mouse models produced by manipulating genes may be used in a variety of fields relevant to neuroscience. It is noteworthy, however, that behavioral studies in mice lag far behind those in rats. For this reason, genetically induced behavioral alterations in mice must be interpreted with caution (Lucki et al. 2001).



Generally, transgenic mice are those expressing exogenous DNA because of the insertion of a gene into the mouse genome. Usually that gene is randomly located within the mouse genome, often as several copies. The use of transgenic mice has represented a major strategy for the investigation of genetic questions since the feasibility and reproducibility of stably introducing DNA by microinjection into individual male mouse embryos were established (Markert 1983). In DNA constructs used for the generation of transgenic mice, the gene of interest is located 3' to promoter sequences to produce a desired distribution of gene expression. The selection of the promoter is the most important consideration in generating transgenic mice. Some promoters, such as platelet-derived growth factor (PDGF), thy1 (a cell surface glycosylphosphatidylinositol-linked glycoprotein), prin (PrP), neuron-specific enolase (NSE), and glial fibrillary acidic protein (GFAP), have demonstrated the ability to direct high-level expression of exogenous genes in brain and/or in the neurons of mice (Hsiao et al. 1996; Kan et al. 2004; Nolte et al. 2001; Sturchler-Pierrat et al. 1997). This level of expression can be modified by incorporation of a "tet-on" or "tet-off" vector into the desired inserted gene. Depending on the nature of the switch (on or off), the mouse will express the gene of interest when ingesting (or taken off) doxycycline.

"Gene targeting" refers to the homologous recombination that occurs between a specifically designed targeting construct and the chromosomal target of interest, in which recombination at the target locus leads to replacement of the native target sequence with construct sequence. The method enables the precise introduction of a mutant into one of many murine genes and has proven invaluable in examining the roles of gene functions in complex

biological processes. Most of the target constructs are used to disrupt a target and to eliminate gene function (conventional "knockout"). Generally, a gene-targeting construct that contains positive–negative selection markers is prepared such that the target gene is interrupted by the gene for neomycin resistance, which also serves as a positive selection marker, and a thymidine kinase (TK; Gusella et al. 1983) gene is adjacent to either one or both ends of the homologous genomic sequence for negative selection. The positive–negative deletion scheme is employed to enrich for homologous recombination.

The targeting construct is often introduced into mouse embryonic stem (ES) cells by electroporation. Cells that fail to integrate the targeting construct into the genome are killed by application of neomycin in the culture medium (positive selection). The majority of the remaining cells, in which the entire construct (including the TK gene) inserts randomly, will die as a result of the incorporation of ganciclovir or fialuridine (inactive thymidine analogs), which block DNA synthesis. Homologous recombinant clones that do not contain the TK gene are used to prepare chimeric mice. Cells from these clones are microinjected into the fluid-filled cavity of 3.5-day-old embryos at the blastocyst stage. The injected embryos are then surgically transferred into the uterus of pseudopregnant females. These animals will give birth to chimeric mice. Breeding can be used to generate mice that are heterozygous and homozygous for the mutation. Homozygous mutants may express the gene of interest in any cell of the body (Figure 2–7).

(A) Producing chimeric mice. First, a mutant allele is produced by replacing the coding exons of the desired gene with a neomycin (neo) cassette and transferring it into embryonic stem (ES) cells. Second, genetically altered ES cells are reintroduced into a developing blastocyst, where they contribute to the developing embryo. **(B) Breeding chimeric mice.** When the germ cells of the resulting chimeric mouse (chimera) are ES cell–derived (germ-line mutation), the heterozygotes

(+/–) can be produced by breeding. One-half of the offspring will be heterozygous. The heterozygous animals may be bred to produce homozygous mice (–/–). TK = thymidine kinase; WT = wild type.

Use of Mutant Mice in Studies of Brain Disease

Transgenic mice produced by this method are generally gain-of-function mutants, because the transgene is designed either to express a novel gene product or to disrupt a normal gene product by expressing a "dominant-negative" alternative. It is also possible to put a DNA fragment in an opposite direction and hence to produce transgenic mice expressing antisense RNA, which will reduce gene function (Jouvenceau et al. 1999; Katsuki et al. 1988). Expression of mutant amyloid precursor protein (APP) or presenilin 1 (PS1) in mice has generated many animal models that may be related to Alzheimer's disease. These transgenic mice have facilitated studies of the pathogenesis, molecular mechanisms, and behavioral abnormalities of Alzheimer's disease (Bornemann and Staufenbiel 2000; Janus et al. 2001). Nevertheless, because the transgene integrates into the mouse genome randomly and often exists as several copies, the interpretation of studies with transgenic mice is difficult.

Experiments with knockout mice have provided novel insights into the functional roles of neuronal genes and, in some cases, animal models relevant to brain disorders. The targeted mutants in a gene of interest, however, can sometime lead to embryonic lethality in mice, thus obscuring the particular role of that gene in a target tissue or in the adult. Furthermore, in some instances, genes related to the gene that was eliminated undergo increased expression in the knockout mice. In this case, the related gene compensates for the gene of interest and yields a phenotype that resembles the "normal" animal. This has been seen for the knockouts of the axonal microtubule-associated protein tau (Takei et al. 2000). Here, we take Huntington's disease to exemplify the use of transgenic mice in the study of neurological and psychiatric disease.

Huntington's disease (HD) is a genetic neurological disorder that is inherited in an autosomal dominant manner. The gradual atrophy of the striatum is its pathological hallmark. It has a prevalence of 3–10 affected subjects per 100,000 individuals in Western Europe and North America (Gil and Rego 2008). The first symptoms generally appear in middle age, and the disease is progressive and invariably fatal 15–20 years after its onset (Ho et al. 2001). HD is caused by an expansion of cytosine-adenine-guanine (CAG) repeats in exon 1 of the *HD* gene. The *HD* gene is located on the short arm of chromosome 4 (4p63) and encodes the protein huntingtin, composed of more than 3,100 amino acids with a polyglutamine tail, which is widely expressed throughout the body in both neuronal and nonneuronal cells.

The function of huntingtin has been revealed with different research approaches, especially those with transgenic mice. Engineered knockout mice that disrupt exon 4 (Duyao et al. 1995), exon 5 (Nasir et al. 1995), or the promoter (Zeitlin et al. 1995) of mouse gene homology, hdh, showed embryonic lethality. A subsequent study using mutant human huntingtin to compensate for the absence of endogenous huntingtin rescued the embryonic lethality of mice homozygous for a targeted disruption of the hdh gene (Leavitt et al. 2001). These suggest its essential role for normal embryonic development. Moreover, condition knockout mice indicated that huntingtin is also required throughout life, because adult mice are sterile, develop a progressive motor phenotype, and with short life span after inactivating hdh gene during adulthood (Dragatsis et al. 2000). Furthermore, overexpression of wild-type huntingtin, bearing 12 glutamine residues, in transgenic mice brought significant protection against apoptosis triggered by NMDA (Leavitt et al. 2006), suggesting that huntingtin may play a role in cellular apoptosis.

As mentioned above, HD is a neurodegenerative disorder caused by uninterrupted CGA trinucleotide repeats that located near the 5'-end in exon 1. Consequently, mutant huntingtin bears a string of consecutive glutamine residues in the NH2-terminal, 17 amino acids downstream of the initiator (Gil and Rego 2008). The length of glutamine residues in NH2-terminal of mutant huntingtin is the primary and predominant determinant for severity of HD. To elucidate the mechanism of neurodegeneration in HD, multiple mouse models of HD have been established. These models vary in terms of the site of transgene incorporation, promoter used, gene expression levels, CAG repeat length, and background mouse strain used. These transgenic models have facilitated investigations into potential pathogenic mechanisms of HD. At present, there are three categories of mouse model:

1. *Mice expressing exon-1 fragments of human huntingtin gene (HD) containing polyglutamine mutations (R6/1, R6/2, and R6/5).* This transgenic mouse carries exon 1 of the *HD* gene with 115–155 CAG repeats. The transgene protein contains the first 69 amino acids of huntingtin in addition to the number of residues encoded by the CAG repeats. Extensive neuropathological analysis has been performed on the brains is R6/2 mice. The mice display subtle motor and learning deficits at approximately 1 month and overt symptoms appear by 2 months, and they usually die at 3 or 4 months (Carter

et al. 1999; Lione et al. 1999; Murphy et al. 2000). It is worthy to note that the characteristic nuclear inclusions were first detected with antibodies against the *N*-terminal portion of huntingtin in R6/2 mice. R6/2 mice show measurable deficits in motor behavior that increase progressively until death. R6/2 mice are a model of *HD* to aim at studying the severity of motor symptoms or the course of the disease. In R6/2 mice, many neurotransmitter receptors, such as NMDA, AMPA, mGluR2, DA, and GABA, display abnormal response to their ligands (Ali and Levine 2006; Cepeda et al. 2004; Cha et al. 1998; Dunah et al. 2002; Starling et al. 2005).

2. *Mice expressing the full-length human HD gene.* Yeast artificial chromosomes (YACs) were used to create a YAC transgenic mouse model of HD that expresses the full-length human HD gene. The transgenic mice express human transgenic huntingtin with 18, 46, 72, or 128 polyglutamine repeats. The YAC mice with 72 CGA repeats develop a progressive motor phenotype, neuronal dysfunction, and selective striatal neurodegeneration similar to that seen in HD by a 12-month timeline. YAC mice with 128 CAG repeats (YAC128 mice) exhibit initial hyperactivity, followed by the onset of motor deficits and finally hypokinesis, which show phenotypic uniformity with low interanimal variability present. The motor deficit in the YAC128 mice is highly correlated with striatal neuronal loss, providing a structural correlate for the behavioral changes (Hodgson et al. 1999; Slow et al. 2003). These lines of transgenic mice may be extremely useful for preclinical experimental therapeutics.
3. *Knock-in HD transgenic mice.* In knock-in mice, a mutated DNA sequence is exchanged for the endogenous sequence without any other disruption of the gene. To establish the line of knock-in HD mice, CGA repeats in the murine *hdh* gene were replaced with human mutant CAG repeats. These mice are characterized by a biphasic progression in behavioral anomalies, and the nuclear inclusions appear late and are preceded by nuclear staining for huntingtin, followed by the presence of microaggregates of the mutant protein in the nucleus and the neuropil (Menalled et al. 2002, 2003, 2005). These knock-in mice are considered to be an ideal genetic model of HD to evaluate the effectiveness of new therapies and to study the mechanisms involved in the neuropathology of HD.

The above examples illustrate both the potential and the current promise of manipulation of the mouse genome for the study of human neuropsychiatric disease.

MICROARRAY TECHNOLOGY

Since the mid-1990s, a new and advanced microarray technology was developed that allows the study of gene expression. This technology is proving to be a powerful research tool for gaining insight into the study of gene expression and gene structure. The main large-scale application of the microarray is *comparative expression analysis.* However, studies of DNA variation are also possible with microarray techniques, as are pharmacogenetics applications.

For DNA microarrays, DNA sequences, DNA inserts of a library from PCR amplifications, cDNA clones, or synthetic oligonucleotides can be immobilized on an impermeable rigid support (e.g., glass) in matrix spots. These microarrays can be hybridized to labeled cDNA probes prepared from the mRNA extracted from the cell and tissue of interest. The hybridization of the probe to each array component is measured to provide a quantitative measure of the abundance of each array component in the probe. Currently, oligonucleotide-based DNA chips are generated by the in situ synthesis of short (20- to 30-nucleotide) DNA fragments by either photolithography on a chip (developed by Affymetrix, Santa Clara, CA) or ink-jet technology (developed by Rosetta Inpharmatics, Kirkland, WA). The latter offers more speed in producing an array and increases the number of elements that can be arrayed on a single chip. Hybridization to short oligonucleotides on a chip has a lower threshold of specificity than the older hybridization techniques, but it is a more comprehensive and extremely rapid screening mechanism. The application of DNA microarray technology has been used recently for characterizing gene expression profiles in human diseases, such as multiple sclerosis (Whitney et al. 1999), cancers (Perou et al. 1999), and various neurodegenerative diseases (Ginsberg et al. 2000).

In principle, any type of ligand-binding assay that relies on the product formation of an immobilized capture molecule and a "binder" present in the surrounding solution can be miniaturized, parallelized, and performed in a microarray format (Templin et al. 2002). Many microarray-based assays have emerged; these include studies of DNA–protein interaction in a microarray format (Bulyk et al. 1999), enzyme–substrate arrays (Zhu et al. 2000), and protein–protein binding assays (Zhu et al. 2001). Microarray-based technology is likely to accelerate basic research in the area of molecular interactions and has the potential to change the diagnostic methods used for a variety of human diseases.

CONCLUSION

Rapid advances in the identification of the human genome and in the methodology for genetic manipulation have combined to open a window into the brain. We are accumulating knowledge of human gene mutations and their

connection to neurological and psychiatric diseases at a rapid pace. As genes are being identified, the proteins for which they code are also becoming known. With this knowledge, the pathogenic mechanism of some diseases is becoming apparent. Understanding these maladies at the molecular level is likely to lead to new methods of diagnosis and novel approaches to therapy.

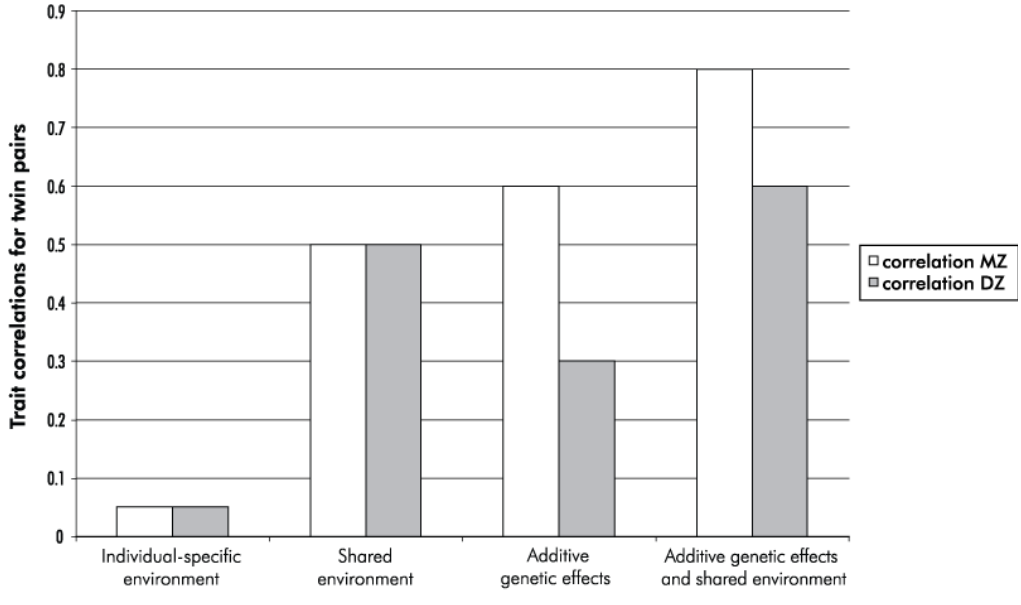
Chapter 3. Genetics and Genomics

GENETICS AND GENOMICS: INTRODUCTION

Genetics and genomics have become among the most important tools in modern psychiatric research. Spurred by the completion of the human genome sequence in February 2001, the number of psychiatric genetic studies has increased dramatically in the past two decades (Lander et al. 2001; Venter et al. 2001). The following chapter will attempt to cover the basic methodologies and concepts, and define key terms, currently used in psychiatric genetics and genomics. Our goal is to facilitate interpretation by working physicians and scientists in the field of psychopharmacology of the avalanche of genetic and genomic data that are accumulating in the human neuroscience literature. Throughout this chapter, terms in common use in the genetics and genomics literature will be italicized upon their first use and definition.

EPIDEMIOLOGICAL BASIS FOR GENETIC CONTRIBUTIONS TO NEUROBEHAVIORAL DISORDERS



Insights From Adoption and Twin Studies

Genetic epidemiological studies have established that most psychiatric disorders, as well as many nonpathological human behavioral traits, have a substantial genetic component. Investigations in genetic epidemiology therefore provide the scientific foundation for molecular genetic and genomic studies of human behavior and behavioral disorders (Kendler 1993, 2001; Plomin and Kosslyn 2001). Genetic epidemiology uses family, twin, and adoption studies to assess the contribution of familial, environmental, and genetic factors to a trait of interest. Family studies can establish that a given disorder "runs in families" but cannot easily distinguish whether such familiality is due to genetic or environmental factors. An everyday example of the distinction between *genetic* and *familial* (but environmental) traits is the difference between the ability to acquire language (a *genetic* trait that distinguishes humans from other species) and the native language spoken by a given person, which is *familial,* but entirely environmentally determined.

Adoption and twin studies distinguish between genetic and environmental influences on traits by accounting for each separately. Adoption studies investigate whether an individual's risk for a psychiatric disease depends on the mental health status of the biological or adoptive parents to disentangle genetic (i.e., similarity to biological parents, who have had little or no interaction with the adoptee) from environmental (i.e., similarity to adoptive parents, who have provided the adoptee with his or her family/social environment) influence (Cadoret 1986; Tienari and Wynne 1994; Tienari et al. 2004). Practical, ethical, and legal obstacles make large-scale adoption studies very difficult to conduct. Twin studies, while also quite challenging, are more tractable, and large twin registries are now available across the world (Busjahn 2002). These studies have provided the bulk of strong evidence supporting genetic contributions to psychiatric disorders and human behavioral traits.

In twin studies one determines what the probability of one twin being affected with a given trait or disorder, given the affectation status of the co-twin. This degree of correlation between twins for the investigated trait is then compared between monozygotic (MZ) and dizygotic (DZ) twins to gain information on the degree of genetic and environmental influence on a certain trait. MZ twins result from a separation of the zygote to yield two genetically identical embryos. DZ twins result from the separate fertilization of two eggs in the same pregnancy. DZ twins thus only share on average 50% of their genes, similar to siblings born in separate pregnancies. While neither the pre- or postnatal environments of twins are perfectly identical, to a first approximation MZ and DZ twins are equally correlated for relevant environmental exposures (Kendler and Gardner 1998). The trait correlation between MZ and DZ twins therefore allows estimation of the degree to which additive genetic, shared, or individual-specific environment contributes to the likelihood of a given trait. Figure 3–1 summarizes relative contributions of each factor, estimated from patterns of correlation between MZ and DZ twins (for a methodological review of this topic, see Bulik et al. 2000).

FIGURE 3–1. Patterns of intrapair correlations and source of variance implied.

Intrapair correlations around zero imply effects of individual-specific environment. Equal intrapair correlations greater than zero that are equal for monozygotic (MZ) and dizygotic (DZ) twins imply effects of shared environment. Correlations for MZ twins that are twice as great as those for DZ twins imply additive genetic effects. Correlations for MZ twins that are greater than—but not twice as great as—those for DZ twins imply additive genetic effects and shared environment effects. The correlations of less than 1.0 in the last three examples are likely mediated by individual-specific environment effects.

Twin studies have firmly established important genetic contributions for all psychiatric disorders, with *heritability* estimates (i.e., the proportion of risk for a disorder attributable to the additive effects of genes) ranging from 30% from 80% for most common psychiatric disorders (see Table 3–1). Interestingly, the importance of shared environment seems to be of significant relevance mostly in schizophrenia, whereas in most other disorders, including anxiety and mood disorders, individual-specific but not shared environment is the major environmental contributor to susceptibility.

Genetic epidemiology can also contribute to the exploration of more complex questions, such as whether genetic risk factors are shared among different psychiatric disorders and gender and whether they can moderate the effects of environmental risk factors (Kendler 2001) and can thus lead the design of follow-up molecular genetic studies. For example, a twin study has suggested that genetic risk factors for major depression could in part act by increasing vulnerability to stressful life events (Kendler 1995). This finding has been corroborated in recent years by the now well-replicated interaction of functional alleles of the locus encoding the serotonin transporter protein with stressful life events to predict depression (Caspi et al. 2003; Kaufman et al. 2004; Kendler et al. 2005; Sjoberg et al. 2006; Surtees et al. 2006; Wilhelm et al. 2006). Genetic epidemiological and more specifically twin studies have therefore been an important foundation of psychiatric genetics and are likely to continue to contribute more elaborate disease models for future molecular genetic analysis. The major limitation of these studies, however, is that the estimated heritability using twin studies is only an estimate of the aggregate genetic effect. Heritability does not give information on the contributions of specific genes to risk for a disorder. These questions, the answers to which ultimately will shed light on the underlying developmental neurobiology underlying psychiatric illness, require molecular genetic methods.

Psychiatric Disorders Are Complex Genetic Disorders

Genetic epidemiological studies have also established that psychiatric disorders are likely not single-gene disorders inherited in a *Mendelian* fashion (i.e., in a clear recessive, dominant, or X-linked fashion), although rare families in which psychiatric phenotypes are inherited this way have been reported (Brunner et al. 1993). A genetic disorder can be complex for several reasons:

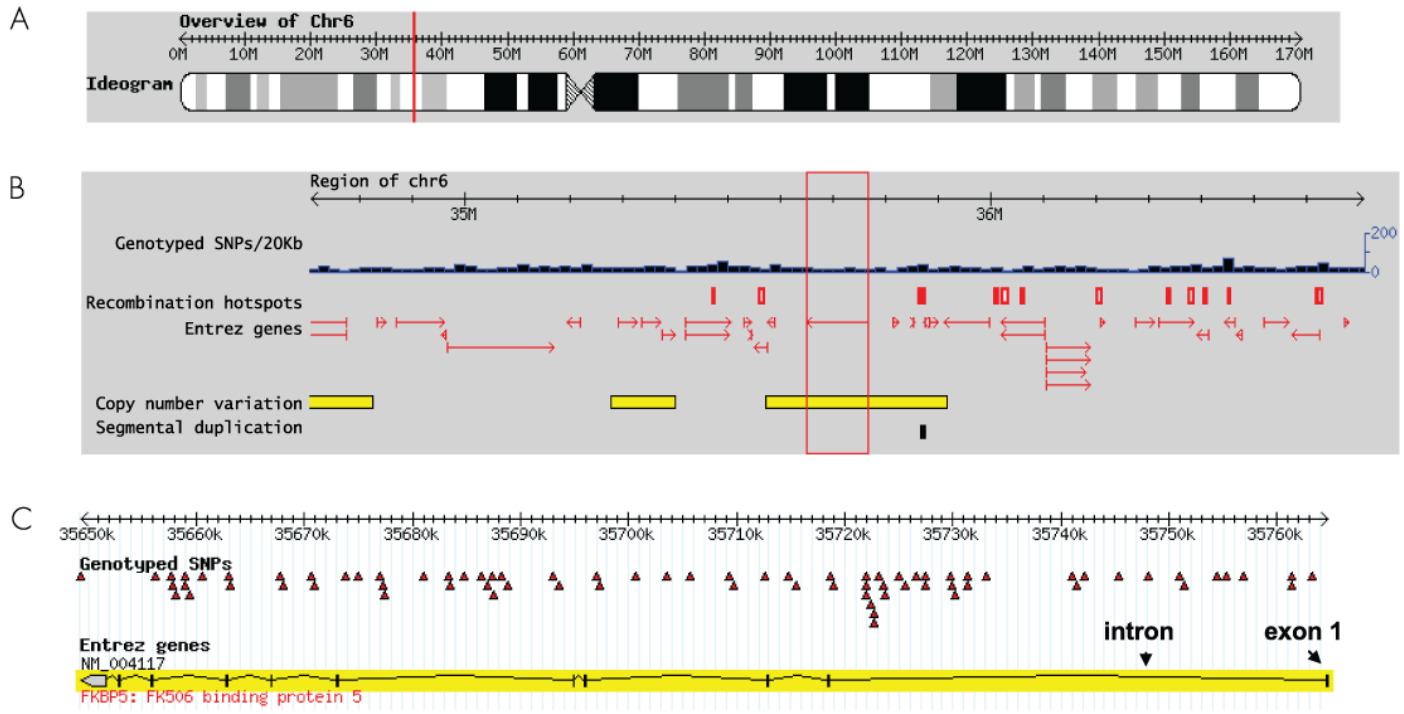
- *Incomplete penetrance.* Not everybody carrying the disease allele(s) becomes ill.
- *Phenocopy.* Individuals, even within the same families, can exhibit similar or identical traits because of environmental factors.
- *Locus heterogeneity.* Variants in different genes can lead to similar or identical disease phenotypes.
- *Allelic heterogeneity.* Different patterns of variation within the same gene or genes can lead to similar or identical disease phenotypes.
- *Polygenic inheritance.* Additive or interactive effects of variation at multiple genes (i.e., *epistatic effects*) are necessary for an illness to manifest.
- *Gene–environment interaction.* A disorder manifests in response to environmental factors only in the context of predisposing genetic variants. An extreme example of such interaction is phenylketonuria, where exposure to dietary phenylalanine causes severe neurobehavioral impairment in individuals carrying two mutant copies of the locus encoding phenylalanine hydroxylase; limitation of dietary phenylalanine prevents the neurobehavioral disorder.
- *High frequency of the disorder and the predisposing alleles.* It appears increasingly likely that common disorders such as schizophrenia, diabetes mellitus, stroke, or hypertension represent final common outcomes to a variety of combinations of environmental and genetic predisposing factors. Thus, two individuals, even within the same family, might manifest clinically indistinguishable disorders for different reasons.
- *Other genetic mechanisms of inheritance.* Alternative genetic mechanisms—for example, mitochondrial inheritance or alteration of the genome across generations, such as occurs in trinucleotide-repeat-expansion disorders (e.g., Huntington's disease, fragile X syndrome) or in epigenetic disorders—may be operable in producing a disorder. *Epigenetic disorders* result from alterations in the genetic material that do not involve changes in the base pair sequence of DNA. Examples of epigenetic disease include the imprinted disorders Angelman syndrome and Prader-Willi syndrome, in which parent-of-origin–dependent chemical modification of DNA produces different phenotypic outcomes from the same chromosomal deletion. Newton and Duman recently reviewed possible roles of epigenetic mechanisms in the action of psychotropic drugs (Newton and Duman 2006) and in neuronal plasticity (Duman and Newton 2007).

From the cumulative evidence of psychiatric genetic studies so far, one can conclude that psychiatric disorders best fit a polygenic mode of inheritance, with two or more polymorphic loci contributing to these disorders, including unipolar depression (Johansson et al. 2001; Kendler et al. 2006), bipolar disorder (Blackwood and Muir 2001), schizophrenia (Sobell et al. 2002), and autism (Folstein and Rosen-Sheidley 2001). However, it is still relatively unclear how many loci contribute to each disorder. The inheritance of schizophrenia, for example, fits models including only a few loci as well as very large numbers of loci (Risch 1990a, 1990b; Sullivan et al. 2003). Data from gene-mapping studies suggest that different loci are indeed likely to contribute to schizophrenia and bipolar disorder in different individuals or families (meta-analyses [Levinson et al. 2003; Lewis et al. 2003; Segurado et al. 2003]), strongly supporting the hypothesis that locus heterogeneity is an important factor in schizophrenia. Thus, Bleuler (1951) appears to have been correct when he referred to dementia praecox as "the group of schizophrenias."

As already noted, susceptibility genes are likely to interact with environment, gender, and other genes, making the search for genes for psychiatric disorders even more complex (Kendler and Greenspan 2006). Twin studies have produced evidence of genetic interactions with stressful life events predicting major depression (Kendler et al. 1995a) and with early rearing environment to predict schizophrenia, conduct disorder, and drug abuse (Cadoret et al. 1995a, 1995b; Tienari et al. 2004). These gene–environment interactions have now been substantiated by several molecular genetic studies (e.g., Binder et al. 2008; Bradley et al. 2008; Caspi et al. 2002, 2003, 2005), suggesting that future genetic and genomic studies will need to include analysis of both sets of factors. Furthermore, it is likely that there are gender-specific predisposing genes for psychiatric disorders. Data from twin studies suggest that the combined genetic factors predisposing to major depression, phobias, and alcoholism may differ in some respects for men and women (Kendler and Prescott 1999; Kendler and Walsh 1995; Kendler et al. 2001a, 2002, 2006; Prescott and Kendler 2000; Prescott et al. 2000), and this has been supported in molecular genetic studies by the identification of gender-specific loci for major depression (e.g., Abkevich et al. 2003; Zubenko et al. 2002). Finally, gene–gene interactions may be relevant for these disorders (Risch 1990b).

Response to Drug Treatment

In contrast to disease susceptibility, genetic epidemiological studies on responses to psychotropic drugs are rare. There is some evidence from family studies that suggests an important contribution of genetic factors in antidepressant response. Already in the early 1960s, studies on the effects of tricyclic antidepressants (TCAs) in relatives suggested that response to these drugs was similar among family members (Angst 1961; Pare et al. 1962). O'Reilly et al. (1994) reported a



familial aggregation of response to tranylcypromine, a monoamine oxidase inhibitor, in a large family with major depression. These initial reports were followed by only a few systematic studies. Franchini et al. (1998) indicated a possible genetic basis of response to the selective serotonin reuptake inhibitor (SSRI) fluvoxamine in 45 pairs of relatives. In light of these data, some groups have used or proposed to use response to certain antidepressant drugs or mood stabilizers as an additional phenotype in classical linkage analyses for mood disorders in the hope of identifying genetically more homogeneous families (Serretti et al. 1998; Turecki et al. 2001).

Nonetheless, family studies supporting a genetic basis of response to psychotropic drugs are sparse, certainly reflecting the extreme difficulties inherent in conducting well-controlled family studies of therapeutic responses to medications. It has been proposed that genetic modifiers for response to treatment to psychotropic drugs may be easier to detect than associations with disease susceptibility, as the genetic contribution to these traits may be less complex (Weinshilboum 2003). So far, the data are insufficient to support or refute that contention.

HUMAN GENETIC VARIATION

As mentioned above, genetic epidemiological studies can only indicate the presence of an aggregate genetic effect but not which type and how many variations contribute to the effect. This next section will give an overview of the types of variation that occur in the human genome and will provide examples for implications of each of them for psychiatric disorders (see also Figure 3–2).

Panel A shows a representation of chromosome 6 (Chr6), which spans 170 megabases of DNA. **Panel B** shows a zoomed-in representation of the area highlighted in red in panel A. This region contains 31 genes within 2 megabases. Genes can be transcribed from both strands of the DNA. The *arrows* indicate the direction of transcription and translation of the respective genes. In the region shown, three copy number variants (CNVs) have been identified. All three span several genes. **Panel C** shows a zoomed-in representation of the gene for FK506 binding protein 5 (*FKBP5*) highlighted with a red frame in panel B. The gene spans 115 kilobases and is composed of 11 exons (translated into protein). The intervening introns are transcribed into RNA but are spliced out to form the mature mRNA that serves as the template for translation. The transcription start is at exon 1. In this gene, more than 60 SNPs have been genotyped within the HapMap Project. Their positions are indicated by the *triangles*. **Panel D** shows sequence examples for three common polymorphisms.

Variation on a Chromosomal Scale

Variation in Chromosomal Number

The human genome has approximately 3 billion bases that are distributed over 23 chromosome pairs, with 22 pairs of autosomes and 1 pair of sex chromosomes, X and Y. The most obvious genetic variations can be observed at the light microscope level in the karyotype. This approach visualizes metaphase chromosomes using histological procedures, allowing identification of each specific pair of chromosomes and variations in the total number of chromosomes, such as unisomies and trisomies. Several of the known variations of total chromosome number have an associated psychiatric phenotype. For example, Down syndrome is a complex neurodevelopmental disorder that results in variable levels of mental retardation, and in old age, dementia strikingly similar to Alzheimer's disease (Visootsak and Sherman 2007). Down syndrome results from *trisomy 21* (i.e., inheritance of three copies of chromosome 21, due to meiotic nondysjunction during oogenesis. Turner syndrome, in which there is only a single X chromosome (i.e., an XO karyotype), is associated with nonverbal learning disabilities, particularly in arithmetic, select visuospatial skills, and processing speed (Sybert and McCauley 2004).

Translocations

Karyotypic examination and other cytogenetic techniques such as fluorescent in situ hybridization (FISH) can reveal additional large-scale chromosomal

abnormalities, such as translocations, deletions, or duplications of large regions of chromosomes. In a large Scottish pedigree, a balanced translocation between chromosomes 1 and 11 appears causally linked to a series of major psychiatric disorders, including schizophrenia, bipolar disorder, recurrent major depression, and conduct disorder (St. Clair et al. 1990). This *balanced translocation* (which exchanged parts of chromosome 1 with parts of chromosome 11 to produce two abnormal chromosomes, but no net loss of chromosomal material) disrupts two genes at the translocation breakpoint on chromosome 1, termed "disrupted in schizophrenia" (DISC) 1 and 2 (Millar et al. 2000, 2001). Subsequent molecular analysis has provided strong evidence that variation in *DISC1* can alter the risk for schizophrenia; the locus is presently considered by most a "confirmed" schizophrenia locus (Porteous et al. 2006).

Deletions

Microdeletions occurring on the long arm of chromosome 22 have received considerable attention as cytogenetic risk factors for the development of schizophrenia (Karayiorgou and Gogos 2004). The 22q11 deletion syndrome (DS), in which 1.5–3 million base pairs of DNA are missing on one copy of 22q, includes a spectrum of disorders affecting structures associated with development of the fourth branchial arch and migration of neural crest cells (e.g., the great vessels of the heart, the oropharynx, facial midline, and thymus and parathyroid glands). Originally described as distinct disease syndromes prior to the elucidation of their common molecular etiology, 22q11DS includes velocardiofacial syndrome (VCFS), DiGeorge syndrome, and conotruncal anomaly face syndrome. Following an initial report of early-onset psychosis in patients with VCFS (Shprintzen et al. 1992), Pulver and colleagues examined psychiatric symptoms in adults with VCFS (Pulver et al. 1994) and in a cohort of patients ascertained for schizophrenia (Karayiorgou et al. 1995). The latter study identified two previously undiagnosed cases in 200 patients, verified by fluorescent in situ hybridization to carry 22q11 deletions. These findings, together with earlier reports of suggestive linkage of 22q11–22q12 (Gill et al. 1996; Pulver et al. 2000), strongly suggested that a gene or genes in the 22q11DS region could contribute to risk for schizophrenia.

Duplications

Duplications of the long arm of chromosome 15 (15q11–13) are the most frequent cytogenetic anomalies in autism spectrum disorders, occurring in approximately 1%–2% of cases (Cook 2001). This duplication syndrome cannot be clinically differentiated from idiopathic autism spectrum disorders (Veenstra-VanderWeele and Cook 2004), indicating that a complete workup of autism should include testing for this cytogenetic abnormality, as well as for several others (Martin and Ledbetter 2007). Interestingly, deletion of this same region of 15q is associated with Angelman syndrome when the deletion occurs on the maternal copy of chromosome 15, and with Prader-Willi syndrome when the deletion occurs on the paternal chromosome (or more rarely, when two maternal copies of chromosome 15 are present, and the paternal chromosome is missing entirely, a condition known as *maternal disomy*). Both syndromes manifest as quite distinct but dramatic neurobehavioral disorders (Nicholls and Knepper 2001; Vogels and Fryns 2002).

Molecular Variation in the Genome

The majority of genetic and genomic studies in neuropsychiatry conducted to date have examined variation at the molecular level, which would be undetectable with methods appropriate for the kinds of variation described above. To introduce this section, we provide basic definitions of terms.

Definition of Alleles, Genotypes, Haplotypes

The definition of alleles, genotypes, and haplotypes is common to all the types of polymorphisms discussed below. An *allele* is a variation in DNA sequence that occurs at a particular *polymorphic* site on one chromosome. Every individual with a normal set of chromosomes has two alleles for each polymorphism on the *autosomes* (nonsex chromosomes, numbers 1–22). On the sex chromosomes, men have only one allele each for all polymorphisms located on the X and Y chromosomes, whereas women carry two copies of each X-linked allele. A *genotype* is the combined description for the variation at a particular corresponding point on homologous chromosomes and is expressed as two alleles. When the alleles on both chromosomes are the same, it is a *homozygous* genotype. When the alleles differ, it is a *heterozygous* genotype. A *haplotype,* a term derived from abbreviation of "haploid genotype," is the sequence of alleles along an adjacent series of polymorphic sites on a single chromosome. When genotypic data are available from three generations, haplotypes in the third generation can be unambiguously deduced. In the absence of sufficient family-based data (e.g., in case–control studies of unrelated individuals), some haplotypes are ambiguous because the combination of genotypes at the polymorphic sites under study can be explained by more than one set of possible chromosomal arrangements of the component alleles. In such cases, methods such as estimation maximization (EM) can be used to infer the most likely haplotype (Hawley and Kidd 1995; Long et al. 1995).

Copy Number Variation

Genome-scale investigations enabled by the sequencing of the human genome and the advent of microarray-based comparative genomic hybridization have recently revealed a previously unappreciated form of polymorphic variation in the human genome: chromosomal regions containing one or more genes can sometimes be deleted or, alternatively, occur in multiple copies, with the number of copies differing among individuals (Nadeau and Lee 2006; Sebat et al. 2004). Such *copy number variants* (CNVs) occur normally in human populations, and a preliminary map of such variants is now available (Redon et al. 2006). They have recently been associated with marked differences in gene expression (Stranger et al. 2007). CNVs can also be associated with predisposition to disease, including neurobehavioral disorders such as autism and schizophrenia (International Schizophrenia Consortium 2008; Sebat et al. 2007; Stefansson et al. 2008). Research in this exciting new area is in its infancy but has already contributed importantly to the genetics of psychiatric disorders (Cook and Scherer 2008).

Copy number variation of the cytochrome P450 gene *CYP2D6,* which is important for the metabolism of many antidepressants, neuroleptics, and mood stabilizers (Kirchheiner et al. 2004), provides a prominent example of the importance of CNVs to pharmacogenetics. The presence in the genome of copy-number variation at this locus was inferred through biochemical–genetic studies predating the molecular era and was subsequently confirmed by molecular studies. The reported range of copy numbers of *CYP2D6* is from 0 to 13. The number of functional *CYP2D6* gene copies directly correlates with plasma levels of metabolized drugs, such as the TCA nortriptyline (Bertilsson et al. 2002). Patients with 0 or 1 functional copy of the gene attain therapeutic plasma levels of nortriptyline with very low doses and can easily reach potentially toxic concentrations with typical or high doses. Patients with 2–4 copies, on the other hand, would require high-normal doses to even reach therapeutic plasma levels (Kirchheiner et al. 2001). In the case of the one reported patient with 13 gene copies, even high-normal doses did not produce therapeutic plasma concentrations (Dalen et al. 1998).

Insertion/Deletion Polymorphisms

Microscopic insertions and deletions (much smaller than CNVs—on the order of one to hundreds of base pairs [bp]) are another important type of genetic variation. The most famous insertion/deletion polymorphism in psychiatric genetics is a common functional polymorphism in the promoter region of the serotonin transporter gene *SLC6A4,* referred to as the 5-HT transporter gene–linked polymorphic region (*5-HTTLPR*). It consists of a repetitive region containing 16 imperfect repeat units of 22 bp, located approximately 1,000 bp upstream of the transcriptional start site (Heils et al. 1996; Lesch et al. 1996). The *5-HTTLPR* is polymorphic because of the insertion/deletion of the repeat units 6–8 (of the 16 repeats), which produces a short (S) allele that is 44 bp shorter than the long (L) allele. Although the *5-HTTLPR* was originally described as biallelic, rare (<<5%) very-long and extra-long alleles have been described in Japanese and African Americans (Gelernter et al. 1999). Numerous additional variants within the repetitive region also occur (Nakamura et al. 2000). Thus, although most studies continue to treat this complex region as biallelic, this is an oversimplification that may be hiding additional genetic information. The *5-HTTLPR* has been associated with different basal activity of the transporter, most likely related to differential transcriptional activity (Heils et al. 1996; Lesch et al. 1996). The long variant (L allele) of this polymorphism has been shown to lead to a higher serotonin reuptake by the transporter in vitro. It is also noteworthy that the function of this insertion/deletion polymorphism may be influenced by a single nucleotide polymorphism (SNP) that occurs with the L allele (Hu et al. 2006). However a positron emission tomography study could not identify differences in serotonin transporter binding potential by *5-HTTLPR* genotype, even when including the information of the additional SNP, in healthy control subjects or patients with major depression (Parsey et al. 2006). This polymorphism has shown associations with a multitude of psychiatric disorders and related phenotypes. The best established are an association with response to treatment with SSRI (Serretti et al. 2007) and the moderation of the influence of life events on the development of depression (Caspi et al. 2003; Kaufman et al. 2004; Kendler et al. 2005; Surtees et al. 2006; Wilhelm et al. 2006; Zalsman et al. 2006).

Microsatellites: STRs and VNTRs

A very important class of polymorphisms, upon which molecular linkage studies and some association studies were based until very recently, is *microsatellite*

markers, also called *short tandem repeats* (STRs) or *variable number of tandem repeats* (VNTRs). The polymorphisms consist of simple sequences, such as GT or GATA, that are repeated a variable number of times. An individual may thus have 5 GT repeats at a specific locus on one chromosome and 7 such repeats on the other. When these regions are amplified by *polymerase chain reaction* (PCR), a technique for producing many copies of a specific small portion of the genome based on DNA polymerase activity directed by specific DNA sequences, the difference in number of repeats results in differences in the length of the amplified fragments (a difference of 4 bp in the current example), allowing efficient genotyping of these polymorphisms by gel electrophoresis, which separates DNA fragments according to length. About 30,000 of these polymorphisms are now known in the human genome (Kawashima et al. 2006; Tamiya et al. 2005), and they have served as markers for genomewide linkage analysis (see "Linkage Studies" subsection below for more detail). VNTRs, however, not only serve as genetic markers for linkage analysis but also may produce functional variation within genes. An important example of such functional variation is a VNTR in the 3' untranslated region (UTR) of the dopamine transporter gene (DAT). The repeat element consists of a 40-bp sequence that can occur with 3–11 repeats, with 9 and 10 repeats being the most common (Vandenbergh et al. 1992). Different effects of the 9 or 10 repeats on gene expression and DAT binding using single photon emission computed tomography (SPECT) in humans have been reported, although the direction of these differences is controversial (Greenwood and Kelsoe 2003; Inoue-Murayama et al. 2002; Martinez et al. 2001; Mill et al. 2002, 2005; van Dyck et al. 2005; VanNess et al. 2005), with the 9 or the 10 repeat alleles respectively associated with higher expression of the DAT gene and higher DAT binding in different studies. Another example of a functional VNTR (48-bp repeat) is a polymorphism in the third exon of the *DRD4* locus (the locus encoding the D_4 dopamine receptor), which results in a variable number of glutamine residues in the third intracellular loop of the dopamine D_4 receptor protein (Van Tol et al. 1992). The allelomorphic proteins differ in their ligand-binding affinities, but all couple to G proteins (Van Tol et al. 1992). Both polymorphisms have been associated with a multitude of psychiatric and behavioral phenotypes (many of which require further investigation before their validity can be established with confidence).

Single Nucleotide Polymorphisms

The polymorphisms that have revolutionized (not only) psychiatric genetics are SNPs (Altshuler et al. 2000; Sachidanandam et al. 2001). SNPs consist of a single-base difference at a particular site in the genome—in two-thirds of cases, a cytosine (C)-to-thymidine (T) exchange. Although theoretically the presence of all four different bases at an SNP is possible, the vast majority of SNPs have only two alleles, although SNPs with three or four different alleles have occasionally been reported. As of June 2008, close to 10 million SNPs have been catalogued in public databases (such as dbSNP [http://www.ncbi.nlm.nih.gov/projects/SNP]). SNPs are so far the most common type of genetic variation and may represent up to 90% of all genetic variations (although this estimate may need revision as knowledge about CNVs accumulates). Besides being very common (SNPs occur, on average, every 300 bases), SNPs are also amenable to high-throughput genotyping methods (Kim and Misra 2007; Kwok 2000). Since SNPs are common (essentially every gene of interest has a number of known SNPs) and cheap to genotype, they have become the markers of choice for psychiatric genetic studies. SNPs are now replacing STRs in genomewide linkage studies, as more genetic information can be gleaned from 5,000–6,000 common SNPs across the genome than from the 300–400 markers typical of STR-based genome scans. SNPs are also the backbone of genetic association analysis.

Besides serving as genetic markers for chromosomal loci in association studies, SNPs can also have functional relevance themselves. SNPs in regulatory regions can alter the transcriptional regulation of a gene, SNPs in regions relevant for mRNA splicing can alter splice sites, and SNPs in protein-coding exons can encode differences in primary amino acid sequence. Interestingly, when one considers the occurrence of SNPs across the genome, one observes that SNPs are most dense in intergenic and intronic regions, while they are scarcer in putative regulatory regions and exons, suggesting selection against putatively functional variants (Altshuler et al. 2000; Sachidanandam et al. 2001). Within exons, SNPs that will not cause an amino acid exchange due to the degenerate code are called *synonymous* SNPs as opposed to *nonsynonymous* SNPs, which lead to amino acid substitution. One nonsynonymous SNP that has repeatedly been associated with psychiatric phenotypes is a valine-to-methionine exchange at amino acid position 108/158 in the soluble (S) or membrane-bound (MB) form of the catechol-*O*-methyltransferase (COMT) peptide sequence due to a G-to-A exchange at position 472 of exon 4. This amino acid exchange dramatically affects the temperature lability of this enzyme, with the methionine allelomorphic protein having only one-fourth of the enzyme activity at 37°C as the valine allelomorph (Lachman et al. 1996; Lotta et al. 1995). It is presumed that individuals with the Val/Val genotype have a more rapid inactivation of centrally released dopamine than individuals with the other genotypes, following an additive genetic model. This polymorphism seems to impact dopamine transmission, particularly in the frontal cortex, where expression of the dopamine transporter protein is relatively low, and has been associated with differences in executive cognition and functional activity of the prefrontal cortex during working memory tasks (Egan et al. 2001; Goldberg et al. 2003; Joober et al. 2002; Mattay et al. 2003). While it was hypothesized that this polymorphism could also alter the risk for schizophrenia (particularly since COMT resides in the 22q11 region, the deletion of which has been associated with schizophrenia), larger association studies and meta-analyses do not fully support that conclusion (Fan et al. 2005).

IDENTIFICATION OF DISEASE LOCI

These next paragraphs will describe specific examples of the different molecular genetic strategies to identify susceptibility genes for psychiatric disorders. We will also discuss potential problems that hinder the identification of such genes.

Cytogenetic Studies

Disruption of chromosomal integrity by rare events such as balanced translocations has facilitated gene discovery in a variety of diseases and has significant promise for similar applications in psychiatric illness (Pickard et al. 2005). Advances in techniques such as chromosome painting, FISH, and, most recently, genomewide analysis of CNVs using microarrays have made it possible to identify disruptions in chromosomal architecture to single-base resolution, thus facilitating identification of specific genes in families cosegregating mental illness and cytogenetic abnormalities. Such data may then be used to generate testable hypotheses about the role of a particular gene in disease pathophysiology. The *DISC1* and *DISC2*) genes provide clear examples of specific genes implicated in mental illness following their discovery through careful molecular analysis of a cytogenetic anomaly. Since much more work has been published on *DISC1,* we focus on that locus here.

As noted previously, *DISC1* was initially identified by cytogenetic studies in which a large Scottish family with numerous relatives affected by major psychiatric illness was shown to carry a balanced (1;11) (q42;q14.3) translocation that cosegregates with the presence of psychiatric illness. Linkage analysis using psychiatric diagnosis as a phenotype and the translocation as a genetic marker yielded highly significant evidence supporting linkage of the translocation to psychiatric illness, and particularly to schizophrenia (Blackwood et al. 2001; St. Clair et al. 1990). The translocation was shown to disrupt *DISC1* and *DISC2* on chromosome 1 (Millar et al. 2000, 2001), whereas no known genes were disrupted on chromosome 11. *DISC1* was shown to encode a novel protein, with no known related proteins, that subsequently has been shown to play important roles in several key neuronal functions, including axonal transport and regulation of G protein–mediated intracellular signaling (Porteous et al. 2006).

Linkage Studies

In the 1980s and 1990s, many genes for Mendelian disorders were successfully identified using linkage analysis in large families. Linkage relies on the principle that on average, chromosomes from parents differ from those of offspring by only one meiotic crossover event. During *meiosis,* the cell divisions that produce gametes by reducing the diploid genome (i.e., two chromosomes of each pair per cell) to a haploid genome (one copy of each chromosome per spermatocyte or ooctye), homologous grandparental chromosomes (i.e., paternal and maternal to the parents of the offspring of interest) make physical contact and exchange homologous regions (referred to as *crossing over*) to give rise to a new set of chromosomes in which each gametic chromosome is a mix of grandparental sequences. This crossing-over process produces *recombination* that can then be tracked using molecular markers to delineate the ancestral origin of each chromosomal region in the offspring. Classically, linkage studies use anywhere from several hundred up to a few thousand microsatellite markers, evenly spaced across the genome. These markers are then genotyped in large families in which the disease of interest is common. To identify positions in the genome that may be involved in the disease, one tracks whether marker alleles are inherited by affected relatives more often than expected by chance (i.e., linkage tests whether a particular chromosomal region *cosegregates* with the disease). A quantitative measure of the likelihood of a particular pattern of marker–disease cosegregation is the *logarithm of odds (LOD) score.* As the name implies, the LOD score is logarithmic, with LOD = 1 corresponding to 1:10 odds, LOD = 2 to 1:100 odds, and so forth. Because of the high a priori probability that a given region is *not* linked to a given phenotype, a LOD score of 3.3 or greater is usually required before significant linkage is accepted (Lander and Schork 1994). The results of linkage analyses are usually presented as plots of LOD scores at each marker, which are arranged in their known order across

individual chromosomes or the entire genome. These plots show a pattern of peaks and valleys. Linkage peaks identify chromosomal regions (i.e., loci) where the LOD score is high, suggesting a high probability that a disease-linked variant resides nearby. Due to the spacing of the markers and their multiallelic properties, the identified regions are usually large, comprising up to tens of mega bases and harboring dozens of genes (which are then referred to as *positional candidates* because they reside under the linkage peak). Linkage peaks need to be followed up with additional *fine mapping* using denser marker maps, including SNPs, to narrow in on the candidate gene(s) of interest.

While classical linkage approaches have been very successful in identifying monogenic diseases that follow clear, simple patterns of inheritance, they have been far less successful in complex psychiatric disease. Parametric linkage analysis requires the specification of an inheritance model (e.g., recessive or dominant), information we do not have for psychiatric disorders as they clearly do not follow Mendelian inheritance. In addition, each family may have a different pattern of inheritance, so that specifying one model for several pedigrees may decrease the power to detect a signal in some of the families. Nonparametric linkage analyses that are mode of inheritance independent have been developed to address this problem. Also, linkage analysis requires that each person in a pedigree be designated as either affected or unaffected, so one must decide, for example, in which category to place individuals with a single major depressive episode in a bipolar pedigree. Linkage analysis studies therefore often run several different models and may also use different definitions of affected status and then report the best LOD score, but here the threshold for significance also has to be adjusted for additional multiple testing, so that even higher LOD scores are required for statistical significance. Linkage analyses in psychiatric disorders are further complicated by the fact that they explore complex psychiatric diseases, with likely multiple (possibly additive or interacting) susceptibility genes and a strong environmental component, all of which cannot be modeled easily in these analyses. It is therefore not surprising that linkage analyses have yielded very inconsistent data in the past. In an effort to overcome these problems by sheer sample size, large meta-analyses have been conducted for linkage scans in schizophrenia and bipolar disorder (Badner and Gershon 2002; Levinson et al. 2003). In schizophrenia, for example, 20 scans with 1,208 pedigrees and 2,945 affected individuals have been used for a combined analysis (Lewis et al. 2003). This study yielded a locus on chromosome 2 segregating with schizophrenia with genomewide significance after correction for multiple testing, and 10 further regions have been identified as strong schizophrenia candidates. A similar meta-analysis was also conducted for bipolar disorder (Segurado et al. 2003), with 948 affected when bipolar I and schizoaffective disorder, bipolar type, were included as diagnoses and 1,733 when bipolar II disorder was also included. In this analysis, none of the linkage peaks reached genomewide significance. These findings suggest that in bipolar disorder the effects of individual genes may be small, thus requiring even greater sample sizes, or that heterogeneity across families is substantial.

Association Studies

Association studies are usually performed in case–control studies of unrelated individuals. In such studies, allele frequencies of markers are compared between a case and a control population. Association has been shown to have more power than linkage studies to detect susceptibility genes that exert only a small effect on disease risk (Risch and Merikangas 1996). Considering the strong evidence supporting complex inheritance for most psychiatric disorders, it appears that association studies are the optimal study design to identify and/or test candidate genes for these disorders. Nonetheless, association studies have been fraught with failures to replicate initially reported associations. For example, several meta-analyses of association studies of the *DRD3* locus, encoding the dopamine D_3 receptor, yielded conflicting results on whether a true association exists between an SNP in exon 2, which encodes either serine or glycine at amino acid position 9 (ser9gly), and risk for schizophrenia (Dubertret et al. 1998; Jonsson et al. 2003, 2004; Williams et al. 1998). Critical evaluation of such controversies requires an understanding of several key concepts, which are important for the design and interpretation of association studies.

Linkage Disequilibrium

Association studies rely on the principle that even unrelated individuals share very small stretches of chromosomal DNA derived from a distant common ancestor. In the case of a disease-predisposing mutation, some proportion of ill individuals will share that mutation arising from an original common ancestor. As the variant is passed down from generation to generation, meiotic recombination events will shrink the size of the initial piece of ancestral chromosome that is inherited together with the disease mutation. On these small ancestral stretches of chromosome (perhaps several thousand to several hundred thousand bp in length), nonfunctional "marker" polymorphisms close to the disease mutation will "ride" through generations together with the disease variant. Such markers (SNPs, for example) can thus serve as surrogate "tags" for the disease mutation. Note, however, that as generations pass and individuals become ever more distant relatives (to a point where social/cultural "memory" of genetic relationship is usually lost), different families will produce recombination events at different points near the disease mutation. Therefore, at a population level, unrelated individuals carrying the disease marker will carry variable lengths of DNA on which markers linked to the disease variant ride. Stated another way, unrelated individuals carrying the disease variant will carry *haplotypes* that become more similar to each other as the boundaries of the haplotypes are moved closer to the disease variant. Thus, the closer a marker is to the disease variant, the more likely it is to be originally linked to the variant. When a marker is close enough to a disease marker that the number of recombination events in the population has not yet completely randomized, and the chance is that it is on the same ancestral stretch of DNA (haplotype) as the disease variant, the marker and the disease variant are correlated and are said to be in *linkage disequilibrium* (LD). Knowing the allele of a marker variant in LD with a disease variant can therefore predict the allele of the disease variant (i.e., the marker and the disease variant are not statistically independent).

Several factors influence the length of DNA over which LD occurs. The most important are the geographic origins of the population from which an individual is drawn and the history of that population. For example, sub-Saharan African populations are ancient and reflect the greatest proportions of the total human pool of variation, because most of the human species' history predates migration of humans out of Africa. Therefore, on average, sub-Saharan African populations have undergone the greatest number of recombination events since a given pair of unrelated individuals shared a common ancestor. Those individuals thus share only short stretches of ancestral chromosomes (which are said to be *identical by descent,* or IBD). Non-African populations all derive from a relatively small number of migrants who left Africa within approximately the last 100,000 years. Thus, Europeans, or Eastern Asians, or Native Americans share longer stretches of DNA IBD within their respective continental groups than do sub-Saharan Africans (Daly et al. 2001; Gabriel et al. 2002; Patil et al. 2001; Reich et al. 2001). On the other extreme, individuals from reproductively isolated populations, in which a small recent founder population has expanded with little admixture (i.e., introduction of outside individuals into the mating pool), share longer blocks of ancestral chromosomes IBD (Shifman and Darvasi 2001). An example of such an isolate is the Icelandic population, which derives almost exclusively from a small number of migrants who arrived on the island only several hundred years ago (Helgason et al. 2003).

Another factor contributing to the complexity of patterns of LD is the fact that recombination events do not occur with the same likelihood across all parts of the genome (Phillips et al. 2003; Reich et al. 2002). In addition to a general pattern in which more telomeric regions of chromosomes are more likely to recombine than centromeric regions, specific "hot spots" of recombination have been identified that are spaced unevenly along chromosomes. This variation across the genome in the likelihood of recombination results in the observation that there are stretches in the genome (sometimes referred to as *blocks*) that have undergone relatively little recombination over the generations and therefore exhibit strong LD among SNPs in the region. Such regions of high LD can span millions of bases, whereas other regions in the same population have recombined more frequently, resulting in very short blocks of LD (e.g., <5,000 bp). It is important to note that the observed haplotypes formed by the SNPs within a given stretch of chromosome usually represent only a small proportion of all possible haplotypes (for SNPs, the number of possible haplotypes = 2^n, where n = the number of SNPs defining the haplotype). For this reason, such regions of high LD are also called *haplotype blocks* (Daly et al. 2001; Gabriel et al. 2002; Patil et al. 2001; Reich et al. 2001).

The HapMap Project

The HapMap Project is cataloguing LD structure (International HapMap Consortium 2003). This international consortium has set out to identify all ancestral or haplotype blocks in four different populations: Caucasian Utah Mormons, Sub-Saharan African Yorubans, Han Chinese, and Japanese. Currently, phase 2 of the project, with genotype data on SNPs with an average density of 1 SNP/ 1,000 bp, is available online (www.hapmap.org). These publicly available data allow identification of the number of SNPs necessary to tag all ancestral blocks for a given gene, region of interest, or even the whole genome (Cardon and Abecasis 2003; Need and Goldstein 2006). While the data generated in this project have been invaluable for the field, one has to evaluate carefully whether the LD structure of the populations characterized in HapMap is representative for the selected study population. HapMap tag SNPs seem to perform reasonably well in most populations, the only caveat being that tag SNPs from Yorubans are not optimal for other African populations, especially African Americans, as they are an admixed population in

which the African ancestors of the population came from a larger geographical area (predominantly along the western coast of Sub-Saharan Africa) than did the Yoruban population (Conrad et al. 2006; de Bakker et al. 2006).

Linkage disequilibrium and replication of association studies

As already noted, the literature contains myriad reported genetic associations to psychiatric disorders that have not replicated in subsequent studies. The most important reason for such nonreplication is that until recently, the vast majority of association studies have been grossly underpowered and have examined only one or a few SNPs. Given the huge a priori odds against a true genetic association at a given locus, even for candidate genes that "make biological sense," many reported associations are likely to be due to chance.

However, even when a disorder-predisposing variant does occur within a candidate gene (i.e., when a true genetic association exists), several factors can lead to nonreplication of association results. Differences in LD patterns between the population of the initial and the replication study can be one reason for such nonreplication. If a marker polymorphism is in strong or complete LD with a true disease-predisposing variant at a given locus, then typing the marker in a sufficiently large case–control study will detect an association to the disease, because the allelic variation at the marker accurately "tags" the true disease-predisposing variant. If an association is detected, then replication is imperative. However, if an independent sample of cases and controls derives from a population with a different ancestry, and hence a different pattern of LD between the marker and the true disease variant, the power of the originally "positive" marker to detect the association can be greatly reduced if the marker does not tag the disease-predisposing variant as well (i.e., power is reduced to the degree that LD between the marker and the disease-predisposing variant is lower). One implication of the foregoing scenario is that adequate evaluation of a given candidate gene requires examination of a number of SNPs across that gene sufficient to represent most of the common sequence variation in the gene: from this principle derives the concept of "tagging SNPs" (International HapMap Consortium 2003; Johnson et al. 2001). Useful software is now publicly available that enables investigators to search the SNP databases and select SNPs that meet a desired criterion of correlation (LD) with each other. Selecting "tagging SNPs" in this way accomplishes two important goals. First, as just discussed, such selection allows the researcher to capture most of the common variation at a candidate gene. Second, selecting tagging SNPs allows the researcher to avoid the unnecessary cost and effort of genotyping redundant SNPs. Among the most useful and widely used software for selecting tagging SNPs is Haploview, developed by Daly and colleagues (Barrett et al. 2005).

One attractive strategy for increasing the likelihood that a given candidate polymorphism is relevant to disease is to focus on variants that clearly alter the structure or regulation of gene products. While it certainly makes sense that polymorphisms that definitely alter protein structure or gene expression (the most obvious type being nonsynonymous SNPs) might be expected to alter more complex phenotypes, it is also quite possible that a presumed functional variant may in fact only be in LD with the real causal mutation. For example, some evidence suggests that the *COMT* Val/Met polymorphism discussed above is merely a marker for an upstream schizophrenia-associated variant (Bray et al. 2003; Shifman et al. 2002). As already discussed, variable LD of the Val/Met variant with some other true schizophrenia-predisposing variant could explain the inconsistent results of the numerous association studies of this polymorphism in schizophrenia.

Stringent testing of the functionality of a specific human polymorphism is currently difficult. Almost invariably, tests of presumed functional variants also examine other known or unknown polymorphisms due to LD with those other variants. Even if correlations with functional readouts are observed, such as changes in expression or function in lymphoblastoid cell lines or differences in imaging parameters, one cannot definitely conclude that the specific polymorphism typed is necessarily the functional one. To test this, one would need to hold all other genetic parameters in the experiment constant and just manipulate the variant of interest on the same ancestral chromosome. So far these very stringent criteria for establishing functionality are rarely met, including for the most commonly genotyped "functional" variants in psychiatric genetics.

One should also note that recent data from the Encyclopedia of DNA Elements (ENCODE) project suggest that the regulation of transcription is much more complicated and widespread than previously assumed (ENCODE Project Consortium 2007). SNPs in *genomic deserts* (no genes close by) may be as important for gene transcription regulation as SNPs located in classical promoter elements.

Population Stratification

Frequencies of specific alleles can vary to a great degree among different populations. The approximate frequency of the S allele of the *5-HTTLPR,* for example, is 40%–50% in European, 70%–80% in East Asians, and 25% in African populations (Gelernter et al. 1999). Spurious associations can thus be found if subjects for a genetic association study are sampled from genetically different subpopulations (with different marker allele frequencies) in different proportions in cases and controls, for example. This could occur if an outcome is more prevalent in one subpopulation, perhaps because of different environmental exposure, so that individuals from this subpopulation will be represented more frequently in the case as opposed to the control group. Differences in allele frequencies between comparison groups can thus result from differences in the population structure of the sample alone, without any causal relationship to the outcome of interest. This problem is called *population stratification* and is exemplified by the hypothetical example of the "chopsticks gene" (Hamer and Sirota 2000).

Several methods have been developed to address population stratification in genetic association studies. Family-based approaches to genetic association studies, such as the transmission disequilibrium test (TDT; Spielman et al. 1993) and the haplotype relative risk (HRR) method (Knapp et al. 1993), are robust to population stratification. In the TDT, rather than compare allele frequencies between cases and controls, genotypes are determined in probands and their parents. To be informative, at least one parent must be heterozygous at the marker of interest (this is one of the disadvantages of the method in its original form: in some cases, not all families can be used). The allele transmitted to the proband from each parent is recorded, as well as the nontransmitted allele. Under the null hypothesis of no linkage or association, the expected chance of each allele's transmission is 50%. Significant deviations from that chance provide evidence for association (and linkage) between the trait and the marker. The HRR method is similar, except that the frequency of the nontransmitted alleles is compared to that of the transmitted alleles over a large number of families. Each family thus provides its own control—since the proband is always matched for the population background of the parents, population stratification cannot arise.

Recently, methods based on the TDT have been developed to allow transmission disequilibrium testing in larger family groups. Such family-based association tests offer the advantage of using more of the available genetic information from each family (Horvath et al. 2001). The major disadvantage of the family-based methods is that it is often impractical to gather families, especially in disorders such as schizophrenia or substance dependence, which are often associated with familial estrangement, or age-related disorders such as Alzheimer's disease, where surviving relatives (especially parents) may not be available. An additional problem with family-based association studies is they generally have less statistical power than case–control studies (Risch and Merikangas 1996).

To control for population stratification in case–control studies, two sets of methods have been developed, both of which estimate, and then correct for, the degree of stratification between comparison groups by typing a series of unlinked markers across the genome (Devlin and Roeder 1999; Pritchard et al. 2000). Using these methods, called *structured association* (Rosenberg et al. 2002) and *genomic control* (Devlin and Roeder 1999), one can only determine stratification of the level of the whole sample. A refinement of these methods employs ancestry informative markers (AIMs), which can estimate the proportional genetic heritage from predefined ethnicities for each individual (Montana and Pritchard 2004; Parra et al. 2001). As opposed to the first approaches, AIMs are not randomly selected unlinked markers, but markers are chosen to exhibit large differences in allele frequencies between specified populations (Northern Europeans vs. sub-Saharan Africans, for example). Using such markers, one can demonstrate that some populations, such as self-identified African Americans and European Americans, may show substantial admixture of European, African, and (to a lesser degree) Native American chromosomal ancestry (Parra et al. 1998, 2001). Each individual's proportion of predefined chromosomal ancestry can be estimated and then used as a covariate to correct for stratification in association analysis (Frudakis et al. 2003).

Correction for Multiple Testing

The ease and cost-effectiveness with which SNPs or other markers can now be genotyped have led to the advent of whole-genome association studies, in which 100,000–1,000,000 SNPs are typed in large case–control comparisons. This approach, while creating the exciting opportunity to scan the genome in a non-hypothesis-driven manner for genetic associations, suffers from the difficult problem that the number of statistical tests in each association study is enormous, and thus the likelihood of false-positive associations is high. In a simple example, when one performs 100 statistical tests, one would expect that 5 of them would

show a *P* value of <0.05 just by chance. To decrease the likelihood of reporting and following false-positive associations, methods to correct for multiple testing have been developed. The simplest and most common is the Bonferroni correction, in which the alpha level required for statistical significance overall is divided by the number of statistical tests and thus, in this case, the number of tested SNPs. However, because not all SNPs are independent (see "Linkage Disequilibrium" subsection above), Bonferroni correction is often overly conservative. Newer methods of correcting for multiple testing take into account the LD among the tested SNPs (e.g., Nyholt 2004). An alternative is permutation-based methods, in which the outcome status (e.g., case or control status) is randomly assigned and the genotypes remain fixed. The association statistic is recalculated for every permutation, and all *P* values are noted. This allows estimation of the number of *P* values that are as small as or smaller than the *P* value based on the correct assignment of outcome status (Churchill and Doerge 1994). The corrected empirical *P* value then is the number of *P* values smaller than the empirical one/number of total iterations. Because permutation-based correction can be computationally intensive, newer, faster methods have been developed (Dudbridge and Koeleman 2004; Seaman and Muller-Myshok 2005). Another method to control for multiple tests is the false discovery rate (Benjamini and Hochberg 1995). In this method one controls the expected proportion of false positives in a list of potential positive associations. It is a less conservative comparison procedure with greater power than the methods mentioned above but at a cost of increasing the likelihood of obtaining type I errors.

While stringent correction for multiple testing reduces the likelihood of reporting false-positive associations, true association may be dismissed as false positives because, while nominally significant, the association does not reach the set threshold for correction for multiple testing. Some researchers thus advocate a two-step design for association studies, in which a first sample is used as an exploratory sample, in which the alpha levels are more liberal, and then nominally associated SNPs are tested in a second replication sample. Only associations that show significance in both samples are considered as potential true positives. This approach has, for example, been used in the pharmacogenetic association study of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) sample (McMahon et al. 2006).

Genomewide Association Studies

New Possibilities Due to the Human Genome Project

Despite 30–40 years of intense research on a series of promising markers, none has thus far been validated as diagnostic tools or predictors of treatment response. In addition, most of the past approaches were hypothesis driven, relying on our limited knowledge of the pathophysiology of psychiatric disorders. With the sequence of the human genome having being publicly available since February 2001 (Lander et al. 2001; Venter et al. 2001), an array of novel research tools has become available that may yield unbiased, hypothesis-free insight into the pathophysiological underpinnings of certain psychiatric disorders. These novel tools combine knowledge of the sequence of the human genome with miniaturized assays amenable to high-throughput processing for a parallel analysis of the whole genome. Using these, one can investigate the whole genome at the level of the DNA (genomics), all expressed mRNA (expressomics—or, more commonly, expression array or microarray analysis), and all proteins (proteomics) in a single experiment. These three approaches have to deal with increasing levels of complexity, because the approximately 25,000 predicted human genes are expected to give rise to at least 10 times as many protein isoforms with a multitude of posttranslational modifications, such as phosphorylation and glycosylation. Using these unbiased whole genome–based approaches, novel pathways and molecules involved in the pathogenesis of psychiatric disorders may be identified. This chapter will mostly focus on genomewide SNP association studies and their impact on psychiatric genetics; we recommend several reviews on the impact of microarray analysis and proteomics on pathophysiological concepts in psychiatry (Freeman and Hemby 2004; Ginsberg et al. 2004; Mirnics et al. 2006; Tannu and Hemby 2006) for additional information in these areas.

Genomewide SNP Arrays

How many SNPs?

The presence of linkage disequilibrium in the human genome allows the investigator to evaluate a large extent of the common genetic variation with selected markers. Estimates of the number of SNPs necessary to account for most of the common sequence variation across the genome (e.g., to account for SNPs with minor allele frequencies of 1% or greater) have varied over time, with estimates ranging from as few as 10,000–100,000 to over a million SNPs. Thanks to the HapMap and the ENCODE resequencing projects (International HapMap Consortium 2003 and www.hapmap.org), we are starting to have a better idea of how efficiently we have and can cover the genetic information using SNP assays. These massive genotyping and resequencing projects have confirmed the segments of long LD in the genome and thus the possibility of using tag SNPs (see discussion above) for each of these segments. Using the data from several hundred thousand SNPs should be sufficient to cover most common variants in Caucasians; more SNPs will be necessary in African populations with shorter LD distances (for a review, see Hirschhorn and Daly 2005). Based on the information in the HapMap and ENCODE databases, Barrett and Cardon (2006) estimated the coverage of commercially available whole-genome SNP panels from Illumina (www.Illumina.com) and Affymetrix (www.affymetrix.com). The Illumina 300k chip offered coverage of 75% in Caucasians and the Affymetrix 500K 65%. These values dropped dramatically for Yorubans, to 28% and 41%, respectively. While these whole-genome arrays with 300,000 to 500,000 SNP assays offered relatively good coverage of more common variants, rare SNPs are not well covered. While these earlier arrays still had relatively substantial holes in the genomewide coverage, especially in African populations, the development in this area is exponential. For example, Affymetrix now offers a 1.8 million SNP array, and Illumina a 1 million SNP chip. Incomplete coverage should soon become a problem of the past (Schuster 2008).

A major drawback of whole-genome LD-based approaches to association testing, such as those just outlined, is that the majority of sequence variation in the genome is *rare,* with minor allele frequencies too small to be detected with any power by even very dense maps of SNPs. Thus, to the degree that the genetic underpinnings of complex diseases deviate from the "common disease, common variant" hypothesis, whole-genome SNP scans will be inadequate to detect associated genes (Zwick et al. 2000). This concern is not merely theoretical. Thus, it is abundantly clear that in Mendelian diseases, such as cystic fibrosis, where variation at only one *locus* accounts for the disease, a multitude of very rare *sequence variants* are causal in different families. Rare variation also clearly contributes to complex diseases. For example, in familial autism, a subgroup of families who exhibit linkage to markers on chromosome 17q (Sutcliffe et al. 2005) has demonstrated that a series of rare functional variants at *SLC6A4,* the serotonin transporter locus, accounts for much of the observed linkage in these families. Common variation at the locus (e.g., the *5-HTTLPR* discussed above) did not contribute to linkage to the disorder in these families. In all likelihood, complex disorders will represent a mixture of contributions from rare and common variants, so that methods appropriate for both types of variation will need to be developed and implemented. In regard to rare variation, the advent of whole-genome resequencing may contribute importantly to identifying such variants.

How many individuals?

Genomewide associations require massive correction for multiple testing so that *P* values below 10^{-7} or smaller have to be achieved for genomewide significance. These necessary low alpha levels, together with the expected low odds ratios (ORs) associated with identified susceptibility variants, require large sample sizes for adequate power. For example, to detect the effect of a susceptibility allele that has a frequency of 20% and an OR of 1.3 with a power of at least 80% and an even more liberal alpha level of 10^{-6}, more than 2,500 cases are necessary. If the allele is rarer (e.g., 10% carriers), at least 6,000 cases would be required (W. Y. Wang et al. 2005). Given that epidemiological studies suggest small effect sizes of multiple genes for psychiatric disorders, these calculations would apply to this field as well.

How to reduce false-positive findings?

Because whole-genome association studies use a large number of tests, very strict levels of significance have been proposed (7.2×10^{-8}; Dudbridge and Gusnanto 2008). While this strategy may avoid a large number of false positives (at least 25,000 SNPs are expected to show association with a *P* value of 0.05 or smaller in a set of 500,000 SNPs), true positives may also be missed. This is especially relevant given that most studies in psychiatric genetics will likely be underpowered to detect relevant effect sizes of 1.3 or smaller with rarer alleles. One possibility to reduce false negatives due to overly stringent correction for multiple testing would be to genotype all SNPs in a smaller fraction of the sample (discovery sample) and use a liberal *P* value to select SNPs that are then genotyped in a second larger sample (confirmation sample). Only SNPs passing this second stage would then be selected for replication in an independent sample (Hirschhorn and Daly 2005; H. Wang et al. 2006). Recently, guidelines for replicating genotype–phenotype associations, with focus on whole-genome associations, have been put forward (Chanock et al. 2007).

Another strategy is to use convergent evidence from other genomewide approaches, such as linkage analyses, expression microarrays, and proteomics. While such studies have not yet been published for whole-genome SNP association studies, this strategy has been successful with microarray and linkage data. John Kelsoe and his colleagues used an approach that combined microarray analysis of animal models of mania and linkage analysis in families with bipolar disorder to identify G protein–coupled receptor kinase 3 (*GRK3*) as a promising candidate gene. This gene is involved in the homologous desensitization of G protein–coupled receptors. The group had initially identified a linkage peak for bipolar disorder on chromosome 22q (Kelsoe et al. 2001; Lachman et al. 1997). That linked region, however, spanned 32 cM, making it a challenging task to identify the causal gene by fine-mapping strategies. The group then used microarray analysis of different brain regions in methamphetamine-treated rats and identified several genes that were regulated by this treatment that also mapped to previous linkage peaks with bipolar disorder (Niculescu et al. 2000). One of these was *GRK3,* which maps to 22q. In addition to being regulated in the animal model, protein levels for this gene were also found to be decreased in a subset of patient lymphoblastoid cell lines, and the magnitude of the decrease correlated with disease severity. By using resequencing and SNP genotyping strategies, the group confirmed the association of 5'UTR and promoter variants of this gene with bipolar disorder (Barrett et al. 2003).

Current Results From Genomewide SNP Association Studies

In a landmark paper, Risch and Merikangas (1996) suggested that genomewide association studies will have more power to detect disease genes for complex diseases than family-based studies. This bold suggestion was postulated 5 years before the sequence of the human genome was available and SNPs emerged as potential tools for this type of study. Now, more than 10 years later, genomewide association studies with hundreds of thousands of SNPs in thousands of affected individuals and controls are identifying novel hypothesis-free candidate genes for complex disorders. In the past few years, a number of large multicenter studies have identified novel candidate genes for diabetes type 1 and type 2, metabolic diseases, several types of cancer, age-related macular degeneration, and a series of autoimmune disorders using this approach (Altshuler et al. 2008). A series of genomewide association studies have now been published for addiction, bipolar disorder, unipolar depression, schizophrenia, autism, and attention-deficit hyperactivity disorder (Psychiatric GWAS Consortium Steering Committee 2009). By early 2009, genomewide association studies in 47 samples from these disorders will be completed, with well over 50,000 independent individuals in these studies. Whole-genome SNP association studies have been successful in bipolar disorder, and polymorphisms in the genes encoding ankyrin G (*ANK3*) and the alpha 1C subunit of the L-type voltage-gated calcium channel (*CACNA1C*) have emerged as new candidates for this disorder from data combining several large samples (Ferreira et al. 2008; Schulze et al. 2008). The latter gene family may also be of relevance in schizophrenia (Moskvina et al. 2008). Interestingly, the independent samples (Baum et al. 2008a, 2008b; Craddock et al. 2008; Sklar et al. 2008; Wellcome Trust Case Control Consortium 2007) mostly yielded no genomewide significant associations or could not be replicated in single association studies, showing the importance of large sample sizes for these studies. The single genomewide association study on unipolar depression published by the end of 2008, starting with data from the Genetic Association Information Network (GAIN) initiative of the National Institutes of Health, did not show replication of the strongest, but not genomewide significant hit in five other samples with a total of more than 7,000 cases and controls (Sullivan et al. 2008a). Whole-genome SNP association studies for schizophrenia have also been less convincing than for bipolar disorder (Kirov et al. 2008; Lencz et al. 2007; Shifman et al. 2008; Sullivan et al. 2008b). The largest replication attempt of genomewide association studies in schizophrenia, with more than 16,000 individuals, points to a locus around zinc finger protein 804A (*ZNF804A*) that reaches genomewide significance when patients with bipolar disorder are included in the meta-analysis (O'Donovan et al. 2008). Genomewide genetics studies in schizophrenia seem to point to the importance of a combination of rare and common variants in this disorder, possibly explaining the relative lack of genomewide significant hits in genomewide association studies. A whole-genome association study in schizophrenic patients revealed a colony-stimulating factor receptor (*CSF2RA*) and an interleukin receptor (*IL3RA*) as potential novel candidate genes for this disorder (Lencz et al. 2007). From this study in two independent samples, the authors could identify an association with disease of common haplotypes in these two genes and also discovered an excess of rare nonsynonymous mutations in these genes, thus supporting a model in which both common and rare mutations can contribute to disease susceptibility (Lewis et al. 2003). The importance of rare variants and specifically structural variants in schizophrenia has been underlined by two large international genomewide studies identifying a series of CNVs associated with the disorder, confirming previous hits in neurodevelopmental genes from earlier linkage and candidate gene association studies (International Schizophrenia Consortium 2008; Stefansson et al. 2008).

The first sets of genomewide association data in psychiatric genetics provide new insights into these disorders. Although promising, these new data raise several important issues:

1. *Multiple genes of small effects contribute to psychiatric disease.* To identify these effects with sufficient power, large sample sizes of several thousand cases will be required, and international collaborations are essential.
2. *Comparison with other complex diseases.* The Wellcome Trust Case Control Consortium (2007) has published whole-genome association data for 14,000 cases of seven disorders and 3,000 common controls. In this study, 2,000 cases of bipolar disorder were examined next to cases of coronary artery disease, Crohn's disease, hypertension, rheumatoid arthritis, and diabetes type 1 and type 2. The direct comparison of this association study for bipolar disorder with association in the other tested disorders is very interesting. In bipolar disorder, no really strong clusters of association could be determined. For diabetes type 1, with a similar heritability (around 80%), on the other hand, at least five very strong clusters of association could be identified, and even coronary artery disease and diabetes type 2, disorders with a prominent environmental component and lower heritabilities, showed several clusters of very strong association. Psychiatric disorders may thus be even more complex than other complex disorders. The fact that bipolar disorder, the most heritable affective disorder, did not perform well in the Wellcome Trust Case Control Consortium analysis in comparison with diabetes and coronary artery disease, for example, shows that psychiatric genetics needs to invest in the identification of reliable biological phenotypes that better cluster genetically homogeneous patient groups.
3. *Importance of a mix of common and rare variants, with rare variants likely predominating in autism and schizophrenia.* Linkage and association studies will need to be combined with resequencing studies to identify these rare variants.
4. *Importance of structural variations in psychiatric genetics.* In schizophrenia and autism, investigation of structural variation has proven to be a very powerful tool to dissect the genetics of these disorders (Cook and Scherer 2008; Marshall et al. 2008; Sebat et al. 2007; St. Clair 2009; Szatmari et al. 2007; Weiss et al. 2008). We are awaiting similar studies in other psychiatric disorders.

Gene–Environment Interactions

To date, most genetic association studies have searched for simple associations between sequence variants and psychiatric disorders. This approach ignores the clear reality that environmental factors contribute importantly to psychiatric illness. While many such factors remain unknown, several clearly are known. For example, it is becoming increasingly clear that early childhood traumatic experiences substantially increase the risk of major depression and other mood disorders. In their landmark paper, now replicated by several groups, Caspi et al. (2003) showed that genotype at the *5-HTTLPR* interacts with exposure to early trauma to increase the risk of depression differentially in carriers of the S allele. From a theoretical perspective, searching for such gene–environment interactions makes sense. Thus, any statistical interaction is bound at the upper end of its effect size by the magnitude of the main effects being considered. When environmental factors such as early trauma, which have large effect sizes, are examined together with genetic factors, which are expected generally to have small effect sizes, the result can be greater power to detect gene–environment interactions than main effects of the gene. Thus, an argument can be made (which by no means is accepted by all) that future genetic studies of psychiatric disorders and other complex disorders should be based on models that incorporate both genetic and environmental factors.

CONCLUSION

Taken together, epidemiological, cytogenetic, linkage, and association studies in psychiatric genetics to date paint a picture of highly complex genetic influences on psychiatric disorders. As Kendler (2005) pointed out, the phrase "a gene for. . . " will very likely *not* apply to psychiatric genetics. And, as Kendler went on to note, "The impact of individual genes on risk for psychiatric illness is small, often nonspecific, and embedded in a complex causal pathway" (Kendler 2005, p. 1243). The field may need to adopt strategies that are better adapted to the most likely disease models. In the following we will mention some of the proposed strategies to address this issue.

First, we may need to reconsider the way we define cases or the phenotype of interest. Our current classification schemes are not likely directly reflective of the underlying biology—and thus the genetic determinants—of psychiatric disease. The currently used diagnostic algorithms (DSM-IV-TR [American Psychiatric

Association 2000] and ICD-10 [World Health Organization 1992]) group diagnoses by symptoms and clinical course, characteristics that may reflect not a common biology but rather a final common pathway of several different pathophysiological disturbances. That recognition has led some to propose the use of intermediate phenotypes—including neurophysiological, biochemical, cognitive, and endocrine measures (Gottesman and Gould 2003; Hasler et al. 2004)—in psychiatric genetic studies in order to create biologically more homogeneous subgroups of patients and thus to increase the power to detect case–control associations. Another important consideration is that a number of symptoms are common to several different DSM-IV-TR diagnoses, and the genetic susceptibility to develop these symptoms may be common across disorders. In fact, there is evidence that the major psychiatric disorders may share susceptibility genes. A series of linkage peaks and candidate gene associations overlaps between bipolar disorder and schizophrenia, for example (Craddock et al. 2006), and the cytogenetic disruption of *DISC1* leads to a variety of severe psychiatric disorders, ranging from recurrent unipolar disorder to schizophrenia (St. Clair et al. 1990).

Second, environmental measures should be included more consistently in genetic studies, including whole-genome association studies. Epidemiological (Kendler 1995) as well as molecular genetic studies have now repeatedly demonstrated the importance of gene–environment interactions in psychiatric disease (Caspi and Moffitt 2006). Genetic effects may be obscured by unmeasured environmental effects, so that different environmental exposures in replication samples may be one source of nonreplication of genetic association.

Finally, one should not forget that SNPs are just the most common and convenient type of genetic variant. Other types of variation, such as CNVs, may be equally important (Redon et al. 2006; Sebat et al. 2004). Newer versions of whole-genome arrays now try to cover most copy number variations known to date, and association with these may lead to surprising findings.

Chapter 4. Chemical Neuroanatomy of the Primate Brain

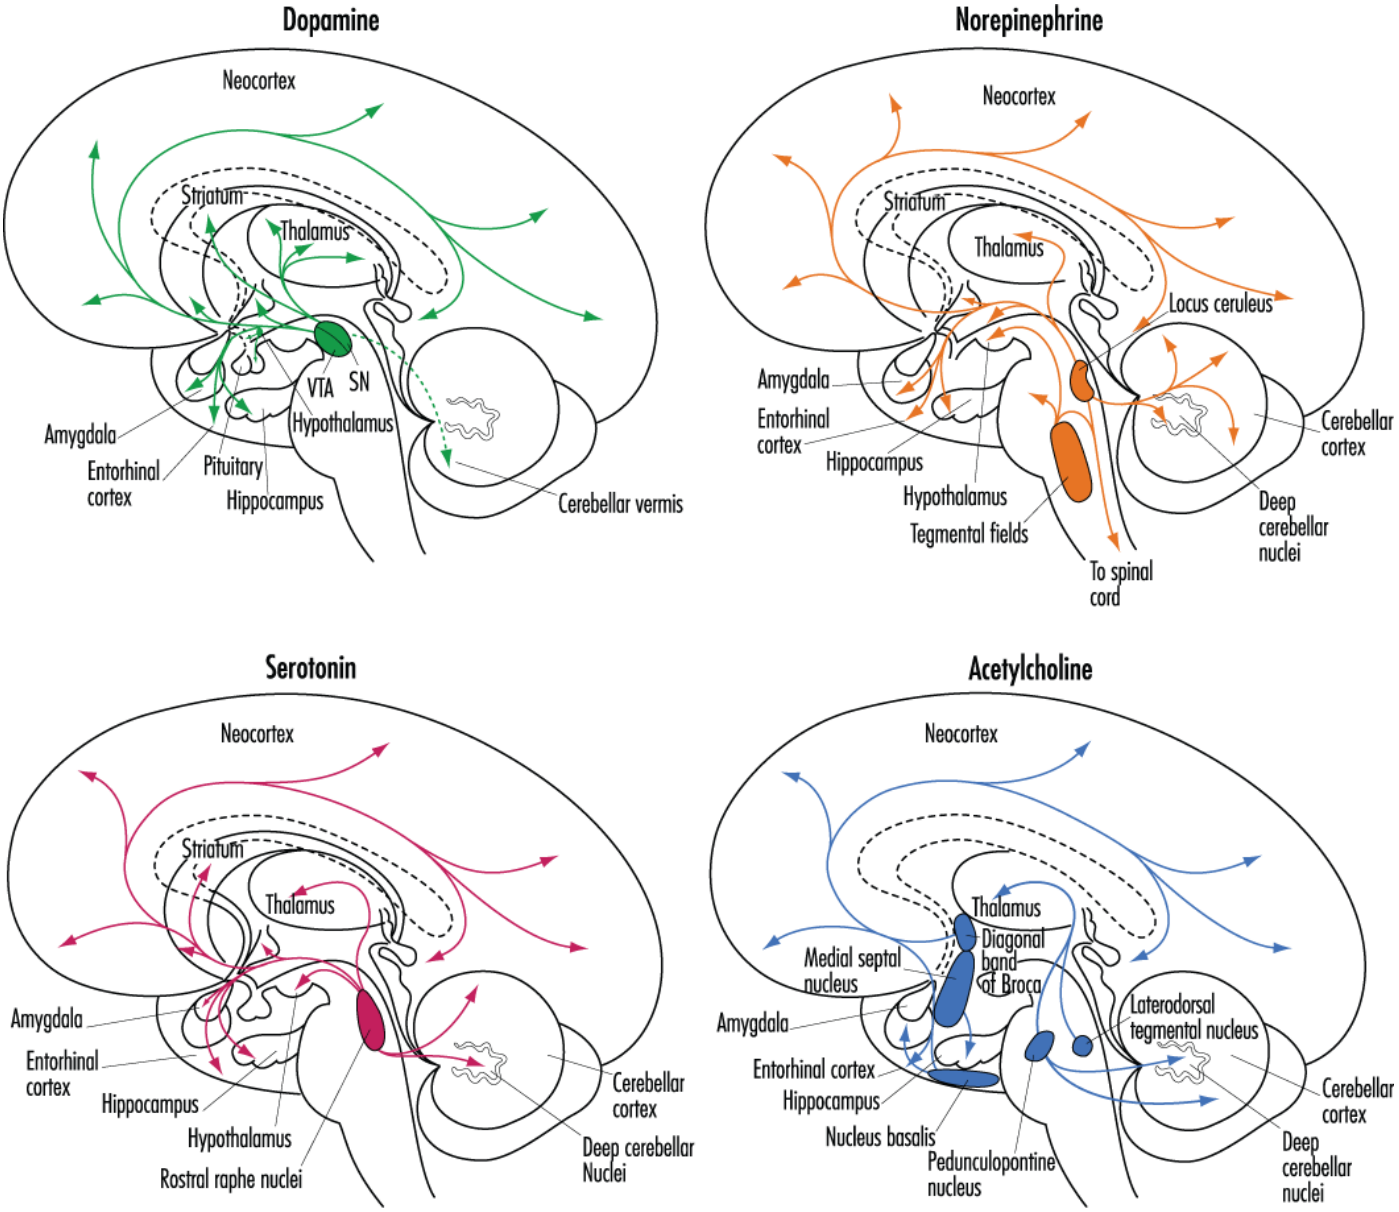
CHEMICAL NEUROANATOMY OF THE PRIMATE BRAIN: INTRODUCTION

Other chapters in this textbook address the questions of how psychotropic medications affect the brain to reduce the severity of the clinical features and symptoms of psychiatric disorders and to produce the side effects that frequently accompany their administration. Appropriately, much attention has been directed toward the neurotransmitter systems that are the targets of these medications. A potential consequence of this emphasis is the idea, in its simplest form, that an excess or deficit in the functional activity of a given neurotransmitter is the pathophysiological basis for the clinical features of interest. Although variants of this view have been very useful in motivating investigations of the molecular underpinnings and biochemical features of neurotransmitter systems and in spurring the development of novel psychopharmacological agents that influence these systems, in the extreme case this perspective tends to consider a given psychiatric disorder as the consequence *solely* of the postulated disturbance in a neurotransmitter system.

In addition to this limited conceptual perspective, neurotransmitter-based views of psychiatric disorders sometimes seem to attribute behavioral, emotional, or cognitive functions to neurotransmitters instead of explicitly recognizing that neurotransmitters have defined actions on receptors, whereas behaviors, emotions, and cognitive abilities represent emergent properties of the integrated activity of large networks of neurons. This view of psychiatric disorders was influenced, at least in part, by extrapolations from earlier successes in the study of Parkinson's disease, which was then viewed as a single-neurotransmitter (i.e., dopamine) disease resulting from a localized neuropathology (e.g., cell death in the substantia nigra).

In recent years, however, greater attention has been given to neural circuitry–based views of psychiatric disorders that reflect a fuller appreciation of the fact that neurotransmitters act in an anatomically constrained fashion to produce specific biochemical effects at the cellular level and that the localization of function(s) is a consequence of the flow of information processing through the neural circuits formed by neurotransmitter systems (Lewis 2002). Consequently, the goal of this chapter is to provide a brief overview of the major neurotransmitter systems of the primate brain, with reference to the rodent brain where appropriate, and to consider these systems within the context of the anatomical pathways in which they participate.

NEUROANATOMY OF THE DOPAMINE SYSTEM



The precursor for dopamine (DA), and all catecholamines, is the amino acid tyrosine. The rate-limiting step in DA synthesis is the conversion of tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase. DA is then formed by decarboxylation of L dopa via the enzyme L-aromatic amino acid decarboxylase. DA neurotransmission is terminated through the actions of the dopamine transporter (DAT) (Jaber et al. 1997), although in some areas where the amount of DAT is low, metabolism also plays a role. The DAT accomplishes this task by transporting DA back into the nerve terminal. DA, and all catecholamines, can also be deactivated by degradation via the enzymes monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT) (Cooper et al. 1996). MAO metabolizes DA into its aldehyde metabolite, and COMT breaks down DA to 3-methoxytyramine. The role of COMT in regulating DA levels appears to depend on brain region (see subsection below titled "Projection Sites") as well as on the presence of two isoforms of the enzyme created by a valine-for-methionine substitution at codon 108/105 in the *COMT* gene (Chen et al. 2004).

Antibodies against DA, tyrosine hydroxylase, and DAT have all been used to map the locations of DA cell bodies, dendrites, and axons (Akil and Lewis 1993; Gaspar et al. 1989; Lewis et al. 1988a, 2001; Williams and Goldman-Rakic 1993). A detailed description of the DA system in the primate brain can be found in Lewis and Sesack (1997).

Cell Locations

The majority of DA cells, which synthesize approximately three-quarters of all the DA in the brain, are located in the anterior midbrain or mesencephalon (Figure 4–1). Although the mesencephalic DA neurons of the primate brain have been parcellated into distinct nuclei, most of these cell groups are interconnected by regions that contain a mixture of cell bodies with different morphological characteristics. These features make it difficult to draw precise boundaries between nuclei, and most investigators agree that DA neurons form a continuum (Moore and Bloom 1978) that extends caudally from the mammillary bodies to the pedunculopontine nucleus.

The *substantia nigra* contains the majority of DA neurons in the primate brain and is subdivided into two main regions, the substantia nigra pars compacta and the substantia nigra pars reticulata (Figure 4–2) (Arsenault et al. 1988; Felten and Sladek 1983). The DA neurons in the substantia nigra pars compacta form a dense zone located in the dorsal region of the substantia nigra. Some DA neurons are located along the dorsal portion of the substantia nigra pars compacta in an area referred to as the pars dorsalis (Poirier et al. 1983). The neurons of the monkey substantia nigra pars compacta are considered to correspond to the A9 region in the rodent (Dahlström and Fuxe 1964). The caudal substantia nigra pars compacta has distinct columns of cells that extend deeply into the ventrally located substantia nigra pars reticulata (Haber and Fudge 1997). Most neurons within the substantia nigra pars reticulata do not contain DA and use γ-aminobutyric acid (GABA) as a neurotransmitter (Smith et al. 1987).

Consistent with its localization to dopaminergic structures, intense DAT immunoreactivity (DAT-IR) is evident in the substantia nigra pars compacta (SNc) and pars reticulata (SNr), as well as in the nigrostriatal projection to the caudate (Cd) and putamen (Pt) nuclei. Also note the marked differences in density of DAT-IR axons across the cortical regions on this section. DAT-IR axons are also present in areas not traditionally thought to contain DA axons, such as the dentate gyrus (DG) and the thalamus (Th). Scale bar = 2.0 mm. CgS = cingulate sulcus; CS = central sulcus; DA = dopamine; LS = lateral sulcus; STS = superior temporal sulcus.

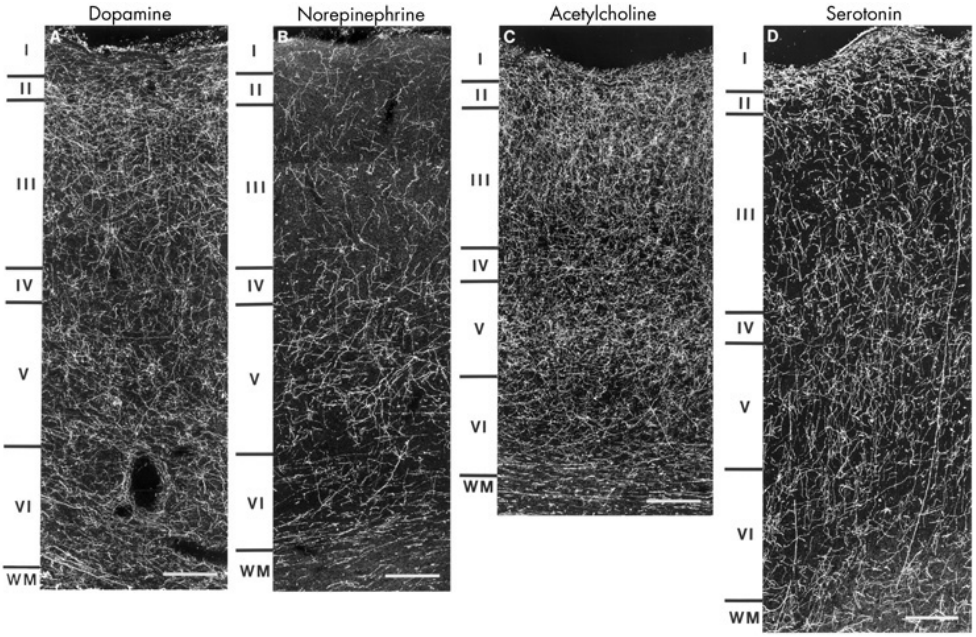
The neurons within these subdivisions of the substantia nigra differ in their expression of the messenger RNAs (mRNAs) for both tyrosine hydroxylase and DAT. For example, the substantia nigra pars compacta neurons have higher levels of both tyrosine hydroxylase and DAT mRNAs than do cells in the substantia nigra pars dorsalis (Haber et al. 1995). This difference is of interest, given that the neurons in the substantia nigra pars compacta and substantia nigra dorsalis project to different brain regions (see subsection below titled "Projection Sites"). Interestingly, tyrosine hydroxylase mRNA levels in the substantia nigra pars dorsalis and ventral cell columns are associated with the COMT genotype. Specifically, individuals with the val/val genotype express higher levels of tyrosine hydroxylase mRNA than do individuals with the val/met genotype (Akil et al. 2003).

The *ventral tegmental area,* which is located immediately medial to the substantia nigra, contains DA neurons that are smaller and less densely packed than those in the substantia nigra pars compacta (Arsenault et al. 1988). This group of neurons corresponds to the A10 group of Dahlström and Fuxe (1964), but the boundaries of this region are less well developed in primates than in rodents. As in the substantia nigra dorsalis, DA neurons in the ventral tegmental area contain lower levels of both tyrosine hydroxylase and DAT mRNA than do cells in the substantia nigra pars compacta (Haber et al. 1995).

A third group of DA neurons, the *retrorubral area,* resides in the caudal midbrain at the level of the medial lemniscus (Arsenault et al. 1988). This group of neurons corresponds to the A8 group of Dahlström and Fuxe (1964). The DA neurons in the retrorubral area are smaller and more dispersed than those located in the substantia nigra (Arsenault et al. 1988).

Several hypothalamic nuclei, including the arcuate, periventricular, paraventricular, and supraoptic nuclei, also contain DA neurons (Arsenault et al. 1988). These DA cell groups correspond to the A11–A15 groups of Dahlström and Fuxe (1964). The DA neurons located within the hypothalamus differ from those located in the mesencephalon in at least two ways. First, the projections of hypothalamic DA neurons are much shorter, extending only to the intermediate lobe of the pituitary and the median eminence. Second, unlike the DA neurons in the substantia nigra, ventral tegmental area, and retrorubral area, most of the DA neurons in the hypothalamus do not express the DAT protein (Ciliax et al. 1995, 1999).

Interestingly, recent studies using large-scale gene expression profiling techniques have revealed differences in gene expression across the various groups of DA neurons (Greene 2006). For example, genes involved in energy metabolism and mitochondria are more highly expressed in neurons of the substantia nigra than in neurons of the ventral tegmental area (Chung et al. 2005). This suggests that DA neurons in the substantia nigra may rely more on oxidative energy metabolism, are under greater metabolic stress, and thus may be more vulnerable to degeneration, such as in Parkinson's disease (Greene et al. 2005).



Projection Sites

The striatum, including the caudate, putamen, and nucleus accumbens, is a major projection target of the DA neurons in the substantia nigra (see Figure 4–2). Indeed, this nigrostriatal projection is the largest DA system projection in the brain. Specifically, DA neurons in the substantia nigra pars compacta provide the majority of this projection, with cells in the substantia nigra dorsalis, ventral tegmental area, and retrorubral area furnishing minor projections to the striatum (Haber and Fudge 1997).

The cerebral cortex is another major projection site of DA neurons, and this projection arises from cells within the substantia nigra dorsalis, ventral tegmental area, and retrorubral area (Lewis et al. 1988b; Williams and Goldman-Rakic 1998). Although early studies suggested that DA projections to the neocortex in the primate were restricted to frontal and temporal regions, it has since been demonstrated that essentially all cortical regions in the primate are innervated by DA axons, although the density of innervation differs substantially across regions (Gaspar et al. 1989; Lewis et al. 1987, 2001; Williams and Goldman-Rakic 1993). In both nonhuman primate and human brains, the motor and premotor cortices, as well as certain areas of the prefrontal (Figure 4–3) and posterior parietal cortices, contain a high density of DA axons. In these areas, DA axons are present in all cortical layers. In the prefrontal cortex, areas 9 and 24 contain the greatest density of DA axons; areas 11, 12, 13, and 25 have an intermediate density; and areas 10 and 46 have the lowest density of DA axons (Figure 4–4). The presence of dense DA innervation in some areas of prefrontal cortex and the well-documented deficits in prefrontal cortical activity in schizophrenia suggest that there may be an abnormality in the DA axons in the prefrontal cortex of patients with schizophrenia. Indeed, postmortem studies indicate that the total lengths of tyrosine hydroxylase- and DAT-containing axons are significantly reduced in the dorsolateral prefrontal cortex of patients with schizophrenia (Akil et al. 1999). These findings suggest that the cortical DA signal might be diminished in schizophrenia as a result of

reduced content of tyrosine hydroxylase per axon, reduced density of DA axons, or both. Other cortical regions, such as association areas in the temporal cortex within the lateral sulcus (see Figure 4–2), contain intermediate levels of DA axons, whereas primary sensory cortices (e.g., visual cortex) generally have low densities of DA axons (Lewis et al. 1987, 2001). Furthermore, DA axons are present only in layers 1 and 6 in the sparsely innervated sensory regions and in layers 1–3 and 5–6 in the regions that have a moderate density of DA axons.

The regional and laminar distributions of DA axons in the primate cerebral cortex differ from those present in the rodent. For example, DA innervation of the rodent cortex is principally restricted to the medial prefrontal and anterior cingulate regions (Berger et al. 1991), in contrast to the widespread DA innervation of the primate cerebral cortex (Lewis et al. 1987, 2001). This expansion of cortical DA innervation in the primate correlates with an increased number of neurons in the ventral mesencephalon (Bjorklund and Dunnett 2007). At the laminar level, DA axons are denser in layers 1–3 in the primate (see Figure 4–3), whereas DA axons in the rodent are confined to layers 5–6. The expansion of DA innervation in primates to additional areas, such as sensory and motor cortices, suggests that DA has additional functions, such as the processing of sensorimotor information, in the human brain, which may be important in movement disorders like Parkinson's disease (Berger et al. 1991).

Ultrastructural investigations of DA-containing axon terminals in the primate cortex have revealed that many do not form conventional synaptic specializations (Beaudet and Descarries 1984; Smiley and Goldman-Rakic 1993). In addition, DA receptors have been identified on spines that are not in direct contact with DA-containing axon terminals (Smiley et al. 1994), and the DA transporter has been localized at a distance from synaptic sites (Lewis et al. 2001; Sesack et al. 1998). For example, in rodent and primate prefrontal cortex, the DA transporter is localized in preterminal axons as opposed to axon terminals (where it is heavily localized in the striatum), limiting the ability of the transporter to regulate extracellular DA levels. In association with this difference, COMT appears to have a more significant role in regulating DA levels in the prefrontal cortex than in subcortical structures (Tunbridge et al. 2004). Polymorphisms in the *COMT* gene lead to protein products with marked differences in enzymatic activity (Chen et al. 2004). Thus, the COMT genotype determines DA levels in the prefrontal cortex and may be important in functions in which the level of DA activity at D_1 receptors plays a role (e.g., working memory). Indeed, individuals with the *COMT* Val allele (high enzyme activity, low DA levels) perform poorly on working memory tasks compared with individuals with the *COMT* Met allele (low enzyme activity, high DA levels) (Egan et al. 2001), and it has been suggested that th e COMT genotype is important in the etiology and pathogenesis of schizophrenia (Lewandowski 2007).

Besides the striatum, other subcortical structures, such as the amygdala and the hippocampus, receive projections from DA neurons. In the amygdala, DA axons originating from the ventral tegmental area and substantia nigra dorsalis are predominantly found in the central, basal, and lateral nuclei (Ciliax et al. 1999). In rodents, a projection from the ventral tegmental area and substantia nigra pars compacta to the hippocampus has been demonstrated. A similar projection has not been reported in primates. However, tyrosine hydroxylase- and DAT-immunoreactive axons have been localized only to the dentate gyrus of the hippocampus in the macaque monkey (Lewis et al. 2001; Samson et al. 1990). DA axons have also been identified in the primate thalamus (Melchitzky and Lewis 2001; Sanchez-Gonzalez et al. 2005) and cerebellum (Melchitzky and Lewis 2000), two brain regions traditionally thought not to receive DA innervation (Moore and Bloom 1978; Steriade et al. 1997). In the thalamus, the mediodorsal, midline, lateral posterior, and ventral lateral nuclei contain the greatest density of DA axons (Melchitzky and Lewis 2001; Sanchez-Gonzalez et al. 2005). Within the mediodorsal nucleus, the ventrolateral portion, which includes both the densocellular and the parvocellular subdivisions, has the highest density of DAT-immunoreactive axons (Figure 4–5). The DA projections to the thalamus arise from DA neurons in the substantia nigra pars dorsalis, ventral tegmental area, and retrorubral area (Melchitzky et al. 2006; Sanchez-Gonzalez et al. 2005) as well as from hypothalamic DA neurons (Sanchez-Gonzalez et al. 2005). The widespread origins of the thalamic DA projections have led to the proposal of a novel dopaminergic system (Sanchez-Gonzalez et al. 2005); however, other evidence indicates that the thalamic projections share anatomical features with the mesocortical DA system (Melchitzky et al. 2006). In the cerebellum, DAT-immunoreactive axons have been localized only to the granule cell layer of the vermis, with lobules VIIIB and IX showing the greatest density of labeled axons (Figure 4–6). Given that both the mediodorsal nucleus of the thalamus and the posterior vermis of the cerebellum are areas reported to be dysfunctional in schizophrenia (Andreasen et al. 1996; Popken et al. 2000; Tran et al. 1998; Young et al. 2000), the identification of DA axons in these brain regions may be of importance to the pathophysiology and treatment of this disease.

Note that both the TH- and DAT-immunoreactive axons are primarily restricted to the granule cell layer (GC), with some clusters of axons extending into the Purkinje cell layer. TH-immunoreactive axons are also present in the molecular layer (ML), but no DAT-immunoreactive axons are detectable in this layer. In contrast, DBH-immunoreactive axons are distributed across all layers. In addition, the restricted lobular distribution of DAT-immunoreactive axons is illustrated by the marked paucity of these axons in the GC *(asterisks in B)* of the folium across the white matter, whereas the density of DBH-immunoreactive axons does not seem to differ across lobules. Scale bar = 150 μm.

Receptors

Five genes encoding five unique DA receptors have been identified. All of these receptors belong to the superfamily of seven-transmembrane-domain G protein–coupled receptors. As implied by the name, the receptor protein spans the plasma membrane seven times, and these receptors are linked to specific G proteins, through which activation of these receptors affects intracellular mechanisms in the postsynaptic cell. Pharmacologically, these receptors can be grouped into two general classes, the D_1 and D_2 subtypes. The D_1 receptor subtype includes the D_1 and D_5 receptors, and the D_2 receptor subtype consists of the D_2, D_3, and D_4 receptors. Interestingly, the D_5 receptor has a 10-fold higher affinity for DA than the D_1 receptor, although the D_1 receptor is more prevalent (described in detail later in this section) (Meador-Woodruff 1994). The D_2 subtype receptors are targeted by many antipsychotic medications.

The mRNAs encoding the different DA receptors have distinct anatomical distributions. The following description of the localization of DA receptor mRNA is based mostly on data from rodents, but data from studies in primates are included when available. In addition, data from autoradiographic and/or immunocytochemical investigations of receptor and protein localization, respectively, are discussed where appropriate. D_1 receptor mRNA is present at high levels in the caudate, putamen, nucleus accumbens, and amygdala and at lower levels in the septal region, hippocampus, thalamus, cerebellum, and cerebral cortex (Hurd et al. 2001; Jaber et al. 1996; Meador-Woodruff et al. 1996). In the cerebellum, D_1 receptor mRNA is expressed in the anterior lobules within the granular cell layer (Mengod et al. 1991). D_1 receptor mRNA is found in all layers of the cerebral cortex, but cortical regions exhibit different laminar patterns (Meador-Woodruff et al. 1991). Brain regions that do not contain D_1 receptor mRNA include the substantia nigra pars compacta and the ventral tegmental area (Meador-Woodruff 1994). In addition, the D_1 receptor has been localized, using a type-specific antibody and immunocytochemistry, in the primate prefrontal and premotor cortices and in the hippocampus (Bergson et al. 1995). In these regions, the D_1 receptor is predominantly located postsynaptically in dendritic spines. The D_1 receptor protein has also been localized to the medium-sized GABA neurons in the caudate nucleus (Bergson et al. 1995). A positron emission tomography study revealed an increase in the binding of NNC112, a D_1 receptor ligand, in drug-free and drug-naive schizophrenia patients, consistent with a compensatory D_1 receptor upregulation in response to reduced DA levels (Abi-Dargham et al. 2002). Thus, both postmortem anatomical and neuroimaging studies indicate decreased DA in the prefrontal cortex of subjects with schizophrenia. Brain regions that do not contain D_1 receptor mRNA include the substantia nigra pars compacta and the ventral tegmental area (Hurd et al. 2001; Meador-Woodruff 1994).

Regions of the brain that contain high levels of D_2 receptor mRNA include the caudate, putamen, nucleus accumbens, ventral tegmental area, and substantia nigra (Hurd et al. 2001; Jaber et al. 1996; Meador-Woodruff et al. 1996). Within the latter two areas, D_2 receptors are predominantly located presynaptically and where they regulate dopamine synthesis and release. The D_2 receptor mRNA is present at lower levels in the septal region, amygdala, hippocampus, thalamus, cerebellum, and cerebral cortex (Jaber et al. 1996; Meador-Woodruff 1994). In the cerebellum, lobules IX and X, which contain DA axons (Melchitzky and Lewis 2000), have the greatest concentrations of D_2 receptor mRNA (Mengod et al. 1992) and also express the D_2 receptor protein (Khan et al. 1998). Limbic regions of the brain, such as the nucleus accumbens, have the highest density of D_3 receptor mRNA in the brain (Jaber et al. 1996; Meador-Woodruff 1994). The substantia nigra, ventral tegmental area, septal region, thalamus, cerebellum, and cerebral cortex contain moderate to low levels of the mRNA for this receptor. In addition, lobules 9 and 10 of the cerebellar vermis express the D_3, as well as the D_2, receptor mRNA (Diaz et al. 1995; Mengod et al. 1992).

The D_4 and D_5 receptor mRNAs are not as highly expressed in the brain as are the mRNAs for the D_1–D_3 receptors (Jaber et al. 1996; Meador-Woodruff 1994). Low levels of D_4 receptor mRNA have been localized to the substantia nigra, nucleus accumbens, ventral tegmental area, hippocampus, amygdala, and cerebral cortex. In addition, the D_4 receptor protein is found in the cerebral cortex and hippocampus, where it is localized to both pyramidal and GABA-containing cells (Mrzljak et al. 1996). The D_5 receptor is the least widely distributed DA receptor, with low levels of mRNA present in the hippocampus, cerebellum, and thalamus (Jaber et al. 1996; Meador-Woodruff 1994). However, visualization of D_5 receptors with a type-specific antibody and immunocytochemistry has revealed that in the primate brain, the D_5 receptor is located in prefrontal, premotor, and mesolimbic cortices, as well as in the hippocampus (Bergson et al. 1995).

NEUROANATOMY OF THE NOREPINEPHRINE SYSTEM

The initial steps in the biosynthesis of norepinephrine (NE) are identical to those for DA. The rate-limiting step is the conversion of the amino acid tyrosine into L-dihydroxyphenylalanine, or L-dopa, via the enzyme tyrosine hydroxylase. NE is then formed from dopamine by the enzyme dopamine-β-hydroxylase. As for the other monoamines, NE neurotransmission is terminated through the actions of the NE transporter protein. A detailed description of the primate NE system can be found in Foote (1997).

Cell Locations

NE-containing neurons in the central nervous system are located predominantly in the medulla and pons (see Figure 4–1). The principal noradrenergic cell

group is the locus coeruleus, the largest group of NE-containing neurons in the mammalian brain. In addition, it is the source of most of the ascending noradrenergic projections. The locus coeruleus is composed of a compact collection of neurons located in the dorsal pons, medial to the mesencephalic tract of the trigeminal nerve. In primate species, NE-containing neurons of the locus coeruleus, like the DA neurons of the substantia nigra, are heavily pigmented with neuromelanin, particularly in mature individuals (Manaye et al. 1995). Consistent with the role of NE in mood disorders, decreases in the neuronal density of locus coeruleus neurons have been reported in postmortem studies of patients with depression (Ressler and Nemeroff 2000).

NE-containing cells are also present in the caudal medulla, including the intermediate reticular zone and the lateral paragigantocellularis nucleus, as well as in the nucleus ambiguus. Collectively, these groups are known as the *lateral ventral tegmental fields* (Cooper et al. 1996).

Projection Sites

The cerebral cortex is a major recipient of noradrenergic projections, specifically those coming from the locus coeruleus (Gatter and Powell 1977; Porrino and Goldman-Rakic 1982). All areas of the cerebral cortex receive these projections; however, certain areas have higher densities of NE axons than other areas. For example, primary somatosensory and visual cortices have a very high density of NE axons, whereas prefrontal cortical areas (see Figure 4–3) are less densely innervated (Lewis and Morrison 1989; Morrison et al. 1982). Within the prefrontal cortex, the distribution of NE axons is similar to that of DA axons, with areas 9 and 24 having the highest density of NE axons; areas 11, 12, 13, and 25 having an intermediate density of NE axons; and areas 10 and 46 having the lowest density of NE axons (see Figure 4–4). These innervation patterns exhibit interesting comparisons and contrasts with those of DA axons. For example, the primary motor cortex contains high densities of both DA and NE axons, whereas the adjacent primary somatosensory cortex contains a very high density of NE axons but a low density of DA axons (Lewis and Morrison 1989; Morrison et al. 1982).

Other brain regions innervated by the locus coeruleus include the thalamus, cerebellar cortex, hypothalamus, and amygdala. Within the thalamus, the different nuclei display varied densities of NE axons. For example, in the primate, the mediodorsal thalamic nucleus contains a high density of NE axons (see Figure 4–5) (Melchitzky and Lewis 2001), whereas the lateral geniculate nucleus is sparsely innervated (Morrison and Foote 1986). By contrast, the different regions of the cerebellar cortex (i.e., the vermis, intermediate zones, and hemispheres) are all moderately innervated by noradrenergic axons (see Figure 4–6) (Melchitzky and Lewis 2000). In addition, unlike the distribution of DA axons, NE axons are found in both the granule cell and molecular layers. Within the hypothalamus and amygdala, the paraventricular and basolateral nuclei, respectively, contain the highest density of NE axons in these structures (Ginsberg et al. 1993; Li et al. 2001).

The noradrenergic nuclei in lateral tegmental fields appear to project exclusively to the brain stem and spinal cord in primates. By contrast, in rodents, these nuclei have been shown to also project to subcortical structures, such as the amygdala and septum (Delfs et al. 2000; Zardetto-Smith and Gray 1995).

Receptors

The receptors that recognize NE, the α and β adrenoreceptors, belong to the G protein superfamily of receptors. Thus, similar to DA, NE elicits responses in the postsynaptic cell via G protein–mediated second-messenger systems. Both α and β adrenoreceptors have two subtypes, namely the α_1 and α_2 adrenoreceptors and the β_1 and β_2 adrenoreceptors (Cooper et al. 1996). All of these receptors are widely distributed across the cerebral cortex, although their regional and laminar patterns differ. For example, in primate prefrontal cortex, autoradiography using appropriate ligands demonstrated that the α_1 and α_2 adrenoreceptors are prominent in layers 1–superficial 3, whereas the highest density of β_1 and β_2 adrenoreceptors is in layers deep 3–4 (Goldman-Rakic et al. 1990). Furthermore, in the human brain, α_1 adrenoreceptors are also present in high density in the cortex, as well as in regions of the thalamus, hypothalamus, and hippocampus (Palacios et al. 1987). Stimulation of α_2 adrenoreceptors in the frontal cortex appears to improve attention, raising the possibility of adrenergic system–targeted therapies for attention-deficit disorders and disorders associated with cognitive deficits, such as Alzheimer's disease and schizophrenia (Stahl 1998).

In the rodent, the mRNA for the β_1 adrenoreceptor is localized to many areas, including cerebral cortex, reticular nucleus of the thalamus, deep cerebellar nuclei, brain stem nuclei, and spinal cord, while the mRNA for the β_2 adrenoreceptor has a more restricted distribution to the olfactory bulb, hippocampus, cerebellar cortex, and intralaminar thalamic nuclei (Nicholas et al. 1993). Autoradiographic studies have also revealed high densities of the β adrenoreceptors in the striatum, the hippocampus and the cerebral cortex in human brain (Pazos et al. 1985). Lower densities of β adrenoreceptors have been found in the thalamus, hypothalamus, and amygdala and the molecular and granule cell layers of the cerebellar cortex (Pazos et al. 1985). Dysregulation of noradrenergic transmission via β adrenoreceptors has been implicated in the pathophysiology of depression. For example, postmortem studies have revealed increased binding of β adrenoreceptors in the frontal cortex of suicide victims (Mann et al. 1986).

NEUROANATOMY OF THE SEROTONIN SYSTEM

Only 2% of the serotonin (5-hydroxytryptamine [5-HT]) in the body is found in the brain. The neurons within the brain synthesize 5-HT, starting with the amino acid tryptophan, which is then hydroxylated via the enzyme tryptophan hydroxylase to form 5-hydroxytryptophan. 5-HT is then formed by decarboxylation of 5-hydroxytryptophan. Similar to DA, reuptake via the serotonin transporter (SERT) is the principal mechanism for terminating serotonergic neurotransmission. SERT also regulates the availability—and hence the signaling potential—of released 5-HT. Consequently, the strength of 5-HT activity at 5-HT receptors is inversely proportional to the number of functional SERT molecules present at the presynaptic membrane. Selective serotonin reuptake inhibitors (SSRIs) and related antidepressant drugs exploit this relationship by blocking the reuptake of 5-HT by SERT, thus increasing the levels of 5-HT in the synaptic cleft. In humans, the gene encoding for SERT exists in both long and short forms, with the short form resulting in lower levels of SERT expression. Azmitia and Gannon (1986) have provided a detailed description of the primate 5-HT system.

Cell Locations

The highest concentration of 5-HT-containing neurons in the mammalian brain is found in the raphe nuclei of the brain stem (see Figure 4–1). The cellular morphology and anatomical distribution of 5-HT neurons indicate that the raphe nuclei can be divided into rostral and caudal brain stem groups in the monkey and human brain stem (Hornung 2003). The principal subdivisions of the rostral raphe nuclei consist of the median raphe, dorsal raphe, and caudal linear nuclei located in the pons and midbrain. The caudal raphe nuclei consist of the raphe pallidus, raphe obscurus, and raphe magnus located in the caudal pons and medulla. The rostral raphe nuclei provide the bulk of the ascending axonal projections to the cerebral cortex and other subcortical structures, whereas the caudal raphe nuclei give rise to descending projections to the lower brain stem and spinal cord (Hornung 2003). Because of the functional and clinical importance of the 5-HT input to the cerebral cortex and limbic forebrain provided by the rostral nuclei, the following anatomical description of the 5-HT system will focus on the rostral raphe nuclei and their axonal projections.

The most rostral 5-HT neurons are located in the interpeduncular nucleus of the ventral mesencephalon (Hornung 2003). The caudal linear nucleus, located dorsal and caudal to the interpeduncular nucleus, lies between the red nuclei and contains both 5-HT and DA neurons. The most diverse of the raphe nuclei is the dorsal raphe nucleus (Baker et al. 1990). It is located in the central gray matter ventral to the cerebral aqueduct and fourth ventricle. On the basis of the topography and density of neurons in the primate, the dorsal raphe can be subdivided into five distinct subnuclei. Of these subnuclei, the ventrolateral subnucleus exhibits the highest density of 5-HT neurons in the entire brain stem (Baker et al. 1990). Postmortem studies have revealed abnormalities such as increased mRNA and protein levels of tryptophan hydroxylase, the rate-limiting enzyme in the synthesis of 5-HT, in the dorsal raphe nucleus of suicide victims (Bach-Mizrachi et al. 2006). The median raphe extends from the caudal midbrain into the rostral pons (Tork and Hornung 1990). Serotonin neurons in the rostral level of the median raphe are densely packed along the midline, whereas at caudal levels, the nucleus expands laterally to form its characteristic barrel-shaped appearance. The barrel-like appearance is formed by the development of the paramedian raphe nuclei, which straddle the midline and contain both 5-HT neurons and 5-HT axons that arise from more caudal levels.

Projection Sites

The cerebral cortex is a major recipient of 5-HT axons arising from the mesencephalon. The heaviest projections to the frontal cortex, including prefrontal (see Figure 4–3) and motor cortices, arise from the dorsal raphe (M. A. Wilson and Molliver 1991). The median raphe and supralemniscal group project equally to the parietal, occipital, and frontal cortices. Unlike DA axons in the DA system, 5-HT axons are homogeneously distributed across different cortical areas, with the greatest density of axons usually present in the middle cortical layers (Morrison and Foote 1986). Furthermore, within cortical areas such as the prefrontal cortex, the density of 5-HT axons across regions is homogeneous (see Figure 4–4).

Although this area has been less well studied in primates, investigations in rodents suggest that the median raphe and dorsal raphe projections to the cerebral cortex are distinct in a number of respects (Mamounas and Molliver 1991). The cortical 5-HT axons originating from the median raphe are characterized by the presence of large spherical varicosities with thin intervaricose segments that give these axons a beaded appearance. In contrast, cortical axons originating from the dorsal raphe are fine and tortuous, with irregularly spaced small varicosities. Most cortical regions contain both types of 5-HT axons; however, the intracortical distribution of 5-HT axons is not uniform. For example, in the primate prefrontal cortex, the fine axons are present in all layers but are more abundant in layers 3–6, whereas the beaded axons predominate in layers 1–2 (Smiley and Goldman-Rakic 1996). These distinct morphological features of 5-HT axons, together with the unique topographical distributions, suggest that different functional roles for the two 5-HT fiber systems may exist. For example, in both rodents and primates, administration of amphetamine derivatives, such as methylenedioxyamphetamine and *p*-chloroamphetamine, causes selective degeneration of fine 5-HT-containing axons, whereas the beaded axons are spared (Mamounas and Molliver 1991; Molliver et al. 1990).

Interestingly, the effects of SSRIs differ based on the brain region and cellular localization of SERT. For example, blocking SERT in 5-HT projection fields (e.g., in the cerebral cortex) increases 5-HT levels and signaling at all available 5-HT receptors. By contrast, blocking SERT at the 5-HT cell body level (e.g., in the raphe nuclei) leads to increased activation of 5-HT_1 autoreceptors (see subsection below titled "Receptors"), ultimately resulting in reduction of overall 5-HT function. Eventually, 5-HT output is increased through desensitization of 5-HT_1 autoreceptors by SSRIs.

With regard to 5-HT synapses in primate cortex, the presence of 5-HT-labeled varicosities does not necessarily correspond to 5-HT synaptic specializations. In fact, it has been reported that more than three-quarters of 5-HT varicosities in the primate cortex do not form identifiable synaptic specializations, even though many had synaptic vesicles and accumulated 5-HT immunoreactivity (Smiley and Goldman-Rakic 1996). These observations suggest that 5-HT release, like that of DA, may occur at sites other than identified synapses and support the concept that nonsynaptic mechanisms of 5-HT neurotransmission are present in the primate cortex.

The raphe nuclei also project to a number of subcortical structures. The rostral group, including the caudal linear and dorsal raphe nuclei, project to the caudate, putamen, substantia nigra, and thalamus. In the primate, the 5-HT innervation of the thalamus is heterogeneous and widespread. The midline, rostral intralaminar, and reticular nuclei are the most densely innervated, whereas the ventral anterior and habenula are sparsely innervated (Lavoie and Parent 1991). The median raphe and the interfascicular subnucleus of the dorsal raphe project to limbic structures such as the hippocampus, amygdala, and septum. Serotonin neurons in both the median raphe and dorsal raphe contain highly collocated axons that innervate multiple terminal fields. This axonal organization pattern suggests that functionally related nuclei can be innervated by the same group of 5-HT neurons or even the same individual neuron.

Receptors

Physiological and biochemical studies have revealed that multiple receptors exist for 5-HT and that many of these receptors have subtypes. To date, 14 5-HT receptors have been identified. The current classification of 5-HT receptors is based on structural characteristics and the second-messenger systems that are utilized. All but one of the 5-HT receptors belong to the G protein receptor superfamily. The exception is the 5-HT_3 receptor, which belongs to the ligand-gated ion channel family (Peroutka 1997).

As with the other monoamine systems, the distribution of 5-HT receptors has been studied mostly in rodents by localization of receptor mRNAs. However, studies conducted in human subjects reveal receptor mRNA distributions similar to those in rodents. The 5-HT_1 receptor has six subtypes, $5\text{-HT}_{1A–F}$ (Peroutka 1997). Several of the 5-HT_1 subtypes—5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D}—appear to also function presynaptically, because the mRNA for these subtypes has been localized to 5-HT-containing neurons in both the dorsal and median raphe. Thus, these receptors also function as autoreceptors, regulating the firing of raphe neurons. In addition, 5-HT_{1A} and 5-HT_{1B} receptors, as revealed by immunocytochemistry and autoradiography, are present in the cerebral cortex as well as other projection sites of the dorsal raphe and median raphe (DeFelipe et al. 2001; Goldman-Rakic et al. 1990; Jakab and Goldman-Rakic 2000; Mengod et al. 1996).

The 5-HT_2 receptor has three subtypes, $5\text{-HT}_{2A–C}$ (Peroutka 1997). The most widely studied of these is the 5-HT_{2A} subtype, the mRNA of which is most abundant in the cerebral cortex. In most cortical areas, layers 1 and 3–4 have a higher density of 5-HT_{2A} mRNA levels than layers 2 and 5–6 (Lopez-Gimenez et al. 2001b). In monkey prefrontal cortex, the 5-HT_{2A} receptor appears to be expressed by pyramidal cells as well as in the parvalbumin-containing subclass of nonpyramidal neurons (Jakab and Goldman-Rakic 2000), which provide potent inhibitory input to pyramidal cells. Subcortical structures, including the caudate, putamen, substantia nigra, and inferior olive, also express 5-HT_{2A} mRNA (Lopez-Gimenez et al. 2001b). The anatomical localization of the 5-HT_{2B} receptor has not been extensively studied, but the cerebral cortex has been shown to contain the mRNA for this receptor (Mengod et al. 1996). The 5-HT_{2B} receptor mRNA is also localized to the cerebral cortex, whereas the 5-HT_{2C} receptor mRNA has been identified in the hypothalamus and medulla (Mengod et al. 1996). The mRNA for the 5-HT_{2C} receptor has been localized to layer 5 of cerebral cortex, nucleus accumbens, caudate, putamen, septal nuclei, diagonal band, ventral striatum, and extended amygdala (Lopez-Gimenez et al. 2001a). Increased binding of both 5-HT_{1A} and 5-HT_{2A} receptors has been found in the prefrontal cortex of suicide victims (Mann et al. 1986), possibly representing an upregulation of receptors due to decreased serotonergic transmission.

The 5-HT_3 receptor mRNA has been identified in rodent cerebral cortex, where it was found to be collocated with GABA-containing neurons (Tecott et al. 1993). In addition, in monkey prefrontal cortex, the 5-HT_3 receptor has been localized to small GABA-containing neurons that also express substance P and the calcium-binding protein calbindin (Jakab and Goldman-Rakic 2000).

The anatomical distribution of the 5-HT_4 receptor has been examined by autoradiography in human brain, and areas with the highest levels of receptors are in the basal ganglia nuclei (caudate, putamen, nucleus accumbens, globus pallidus, and substantia nigra) and the hippocampus, specifically area CA1 and subiculum (Varnas et al. 2003). In neocortex, the superficial layers have higher levels of 5-HT_4 receptor than the deeper cortical layers.

In rodent brain, the 5-HT_7 receptor protein is found in the cerebral cortex, hippocampus, thalamus, and hypothalamus, with a somatodendritic localization in these areas (Neumaier et al. 2001). In human brain, 5-HT_7 receptors, visualized via autoradiography, are also found in the cerebral cortex, hippocampus, and thalamus, as well as in the caudate and putamen (Martin-Cora and Pazos 2004).

The anatomical localization of the remaining 5-HT receptors (i.e., $5\text{-HT}_{5A–B}$, 5-HT_6) has not been as well studied. However, mRNA for these receptor subtypes appears to be predominantly localized to subcortical structures, such as the caudate, nucleus accumbens, hippocampus, thalamus, and amygdala.

NEUROANATOMY OF THE ACETYLCHOLINE SYSTEM

Acetylcholine (ACh) is phylogenetically a very old molecule that is widely distributed in eukaryotic as well as prokaryotic cells. Furthermore, ACh is found in many non-neuronal tissues, in which it appears to modulate basic cellular actions. ACh is formed by the synthesis of acetyl coenzyme A and choline via the enzyme choline acetyltransferase. Acetyl coenzyme A is available from mitochondria, and choline is obtained through the diet. ACh is rapidly inactivated in

the synaptic cleft by the enzyme acetylcholinesterase. The activity of both choline acetyltransferase and acetylcholinesterase is reduced in the frontal and temporal cortices of patients with Alzheimer's disease, and the decrease in choline acetyltransferase activity is associated with the presence of the apolipoprotein epsilon 4 (*ApoE*-ε4) allele (Lai et al. 2006).

The presence of ACh-containing cell bodies and axons has been demonstrated by the use of histochemical procedures to visualize the acetylcholinesterase molecule, as well as by the use of specific antibodies directed against choline acetyltransferase. Immunocytochemical identification of ACh-containing axons using choline acetyltransferase antibodies is the preferred method, because acetylcholinesterase may not be a specific marker of cholinergic structures. A detailed review of the primate cholinergic system can be found in De Lacalle and Saper (1997).

Cell Locations

ACh-containing neurons are located in two main groups in the brain (see Figure 4–1). The basal forebrain cholinergic complex is located near the inferior surface of the telencephalon, between the hypothalamus and orbital cortex. This complex includes the medial septal nucleus, the diagonal band of Broca, the nucleus basalis (also known as the basal nucleus of Meynert), the magnocellular preoptic area, and the substantia innominata. All of these regions are characterized by the presence of large ACh-containing multipolar neurons (Semba and Fibiger 1989).

The pontomesencephalotegmental cholinergic complex consists of the pedunculopontine nucleus, which is located along the dorsolateral aspect of the superior cerebellar peduncle, and the laterodorsal tegmental nucleus in the ventral part of the periaqueductal gray. Similar to the cells in the basal forebrain complex, the pontomesencephalotegmental complex is also characterized by the presence of large ACh-containing cells (Semba and Fibiger 1989).

In addition to these cell groups, ACh-containing neurons are also present in all nuclei of the striatum (i.e., the caudate, putamen, and nucleus accumbens). However, these cholinergic cells are interneurons and thus do not project out of the striatum (Cooper et al. 1996).

Projection Sites

The cerebral cortex is a major recipient of cholinergic projections, which originate predominantly from the basal forebrain complex. The organization of these projections in the primate is similar to that in the rodent. In general, these projections are topographically organized, with a distinct population of neurons projecting to a particular location in the cortex.

The distribution of ACh-containing axons in the cerebral cortex is heterogeneous, with paralimbic areas having the greatest density of ACh-containing axons. The sensory and association regions of neocortex are less densely innervated by cholinergic axons than are the paralimbic areas. For example, in human brain, the density of cholinergic axons is lowest in the primary visual cortex; moderate in association areas, including parts of the prefrontal (see Figure 4–3) and parietal cortices; and highest in the paralimbic entorhinal and cingulate cortices (Mesulam et al. 1992). The density of cholinergic axons also differs within a cortical region. In monkey prefrontal cortex, there is a rostral to caudal increase in the density of ACh-containing axons, so that area 10 at the frontal pole has a lower density of cholinergic axons than does area 9, which is less densely innervated than the more caudal area 8B. Furthermore, the more caudal premotor (area 6) and motor (area 4) cortices have the highest density of ACh-containing axons in the frontal lobe (Lewis 1991). However, cholinergic axons are distributed homogeneously across prefrontal areas at the same rostrocaudal level (see Figure 4–4).

The distribution of ACh-containing axons across the cortical layers is also heterogeneous. In general, layers 1–2 and 5 have the highest density of cholinergic axons, whereas layer 4 has the lowest density of ACh-containing axons (Lewis 1991; Mesulam et al. 1992).

The hippocampus is also densely innervated by cholinergic axons. These projections arise from the medial septal and diagonal band of Broca nuclei of the basal forebrain complex (Kitt et al. 1987). The molecular layer of the dentate gyrus and the CA2, CA3, and CA4 subsectors of the hippocampus contain the highest densities of ACh-containing axons (Mesulam et al. 1992). Although the densities of ACh-containing fibers in the CA1 subsector and subiculum are lower than those in the other portions of the hippocampus, they are still more densely innervated than most cortical areas (Mesulam et al. 1992).

The amygdala also receives projections from the basal forebrain cholinergic complex. Within the amygdala, all nuclei are densely innervated by ACh-containing axons, with the basolateral nucleus having the highest density (Mesulam et al. 1992). Retrograde tracing has demonstrated that this projection principally arises from the nucleus basalis (Kitt et al. 1987).

In the rodent, the reticular nucleus of the thalamus and the interpeduncular nucleus are densely innervated by cholinergic axons originating from the nucleus of the diagonal band of Broca and the nucleus basalis, respectively. These projections have not been investigated in the primate (Semba and Fibiger 1989).

The thalamus is densely innervated by cholinergic axons, which originate from the pedunculopontine and laterodorsal tegmental nuclei (Semba and Fibiger 1989). In addition, acetylcholinesterase activity and immunoreactivity for choline acetyltransferase have revealed a heterogeneous distribution of cholinergic axons within the thalamus. For example, in the primate, the midline, intralaminar, anterodorsal, lateral mediodorsal, and medial pulvinar nuclei contain very high levels of cholinergic axons (Barbas et al. 1991; Cavada et al. 1995). A similar pattern of cholinergic axons is found in the rodent (Levey et al. 1987).

The pedunculopontine and laterodorsal tegmental nuclei project to other subcortical structures, including the lateral hypothalamus, the superior colliculus, and the lateral preoptic area. However, these projections have only been investigated in rodents (Semba and Fibiger 1989).

Receptors

ACh receptors have been divided into two main classes, the muscarinic and nicotinic receptors. There are five (M_1–M_5) subtypes of the muscarinic receptor, all of which are coupled to G proteins and linked to a variety of second-messenger systems. Neuronal nicotinic receptors are formed from five membrane-spanning subunits situated around a central pore. The neuronal nicotinic receptor has two subunits, α and β; the α subunit has seven different forms, and the subunits that form αβ combinations include α_2–α_6 and β_2–β_4 (Dani and Bertrand 2007). Homomeric and heteromeric nicotinic receptors can be formed from the α_7–α_{10} subunits. The nicotinic receptors are ionotropic, acting directly on sodium channels.

Most of the studies investigating the localization of ACh receptors in the brain have employed autoradiography, utilizing tritiated nicotine or receptor subtype-specific ligands. For example, the M_1 and M_2 receptor subtypes have been shown to be present in many regions of the cerebral cortex, including the frontal, parietal, and occipital cortices (Flynn and Mash 1993). Specifically, the overall densities of the M_1 and M_2 receptor subtypes are similar, but the laminar distributions vary across the cortex (Lidow et al. 1989). In parietal, occipital, and motor cortices, both receptor subtypes are concentrated in the superficial layers. In contrast, the M_1 and M_2 subtypes are evenly distributed across the cortical layers in the prefrontal cortex. Subcortical structures show a varied distribution of muscarinic receptors. The striatum has a high density of M_1, M_2, and M_3 receptors, with M_3 receptors localized to the anterior and dorsal caudate nucleus and M_1 receptors more prevalent in the ventromedial caudate and medial globus pallidus (Flynn and Mash 1993). Low levels of M_1 and M_3 receptors are found in the thalamus, hypothalamus, and brain stem. In Alzheimer's disease, M_1 and M_2 receptors, as measured by autoradiography, are reduced in the frontal cortex and hippocampus, respectively, whereas M_3 and M_4 receptors appear to be unaffected (Rodriguez-Puertas et al. 1997).

The distribution of tritiated nicotine binding sites is similar in both rat and monkey brains. For example, in both species, dense labeling occurs in sensory- and motor-related thalamic nuclei, the dentate gyrus of the hippocampus, and layer 3 of the cerebral cortex (Clarke 1989). Furthermore, the anatomical distributions of mRNA for the nicotinic ACh receptor subunits have been investigated in the monkey brain. The α_4 and β_2 receptor subunits are the most widely distributed, with highest densities in the dorsal thalamus and the DA-containing nuclei of the mesencephalon (Han et al. 2000). Consistent with the well-known involvement of the cholinergic system in Alzheimer's disease, the densities of α_4 and β_2 nicotinic receptors are reduced in the temporal and

frontal cortices of patients with this disease (Lai et al. 2006).

Several lines of evidence support a role for the α_7 receptor subunit in the pathophysiology of sensory gating deficits in schizophrenia. For example, a postmortem study has shown that binding of α-bungarotoxin, which most likely corresponds to nicotinic receptors containing the α_7 subunit (Leonard et al. 2000), is reduced in the hippocampus of patients with schizophrenia (Freedman et al. 1995). In addition, sensory gating deficits are improved by nicotine in subjects with schizophrenia as well as in their unaffected family members (Adler et al. 1998). Interestingly, unlike control subjects, who show an upregulation of nicotinic receptors in association with smoking, individuals with schizophrenia exhibit lower binding of nicotinic receptors at every level of smoking history (Breese et al. 2000).

ENDOCANNABINOID SYSTEM

The endocannabinoid system is an endogenous signaling system composed of endocannabinoids, their receptors, and the proteins involved in their synthesis and degradation (Pazos et al. 2005). Anandamide and 2-arachidonoylglycerol, the two principal endocannabinoids in the brain, bind to and activate the G protein–coupled cannabinoid receptors, CB_1 and CB_2. The CB_1 receptor, the predominant endocannabinoid receptor in the brain, mediates most of the behavioral effects of endogenous and exogenous cannabinoids (Zimmer et al. 1999). The CB_2 receptor is principally expressed in non-neural tissues, such as immune system organs (e.g., spleen). CB_1 receptors are located primarily on presynaptic axon terminals and mediate the retrograde signaling of endocannabinoids in synaptic plasticity processes, such as depolarization-induced suppression of inhibition (Alger 2002).

Distribution of the CB_1 receptor is widespread, with many areas of the brain expressing high levels (Figure 4–7). Specifically, the neocortex, hippocampus, amygdala, globus pallidus, and cerebellum all exhibit high densities of the CB_1 receptor (Biegon and Kerman 2001; Eggan and Lewis 2007; Herkenham et al. 1991). Within the primate cerebral cortex, association regions, such as the prefrontal cortex, contain the highest levels of CB_1-immunoreactive axons, whereas primary sensory regions, particularly primary visual cortex, have the lowest densities (Eggan and Lewis 2007). Within the prefrontal cortex, dorsolateral area 46 contains the highest densities of CB_1-immunoreactive axons. The density of CB_1-labeled axons in the hippocampus is similar to that in the prefrontal cortex. Interestingly, within the amygdala, the cortical-like basolateral complex has a higher density of CB_1 axons than does the striatal-like central and medial nuclei (Figure 4–7). Of the basal ganglia nuclei, the globus pallidus has the highest and the striatum the lowest levels of CB_1 immunoreactivity. As is evident in Figure 4–7, the thalamus is completely devoid of CB_1 axons.

FIGURE 4–7. Brightfield photomicrograph of a coronal section through macaque monkey brain illustrating the distribution of cannabinoid CB_1 receptor–immunoreactive axons.

Association areas such as the cingulate cortex (area 32), insula (Ig, Idg), auditory association cortex (RP), and entorhinal cortex (E_I) have an overall higher density of CB_1-immunoreactive axons than do primary somatosensory areas (areas 3, 1, 2) and primary motor cortex (area 4). Note the distinct differences in laminar distribution of labeled processes at the boundaries of some cytoarchitectonic regions *(arrows).* In subcortical structures, the intensity of CB_1 immunoreactivity is high in the claustrum (Cl), the basal and lateral nuclei of the amygdala, and both segments of the globus pallidus (GP); intermediate to low in the caudate (Cd) and putamen (Pu) and the central and medial nuclei of the amygdala; and not detectable in the thalamus (Th). In the neocortex, the CB_1 receptor is highly expressed in the subpopulation of GABA-containing inhibitory interneurons (Marsicano and Lutz 1999) that also synthesize the neuropeptide cholecystokinin (Bodor et al. 2005). In addition, in rodent hippocampus (Katona et al. 1999) and monkey prefrontal cortex (Melchitzky et al. 2007), CB_1-immunoreactive axons have been shown to be collocated with cholecystokinin. This association of CB_1 with GABA neurons in the prefrontal cortex suggests that the endocannabinoid system may be involved in cognitive processing as well as in disorders characterized by impaired cognition, such as schizophrenia. Indeed, cannabis use impairs cognitive processes such as working memory (D'Souza et al. 2004) and has been associated with an increased risk for schizophrenia (Smit et al. 2004). In addition, a reduction in CB_1 mRNA levels in the prefrontal cortex of subjects with schizophrenia (Eggan et al. 2008) provides further evidence for a role of the endocannabinoid system in the pathophysiology of schizophrenia.

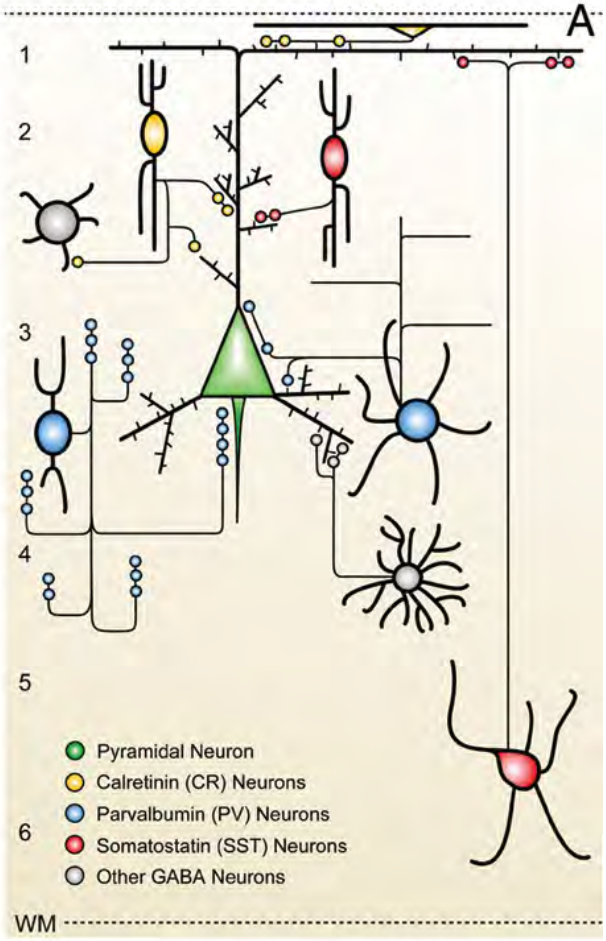
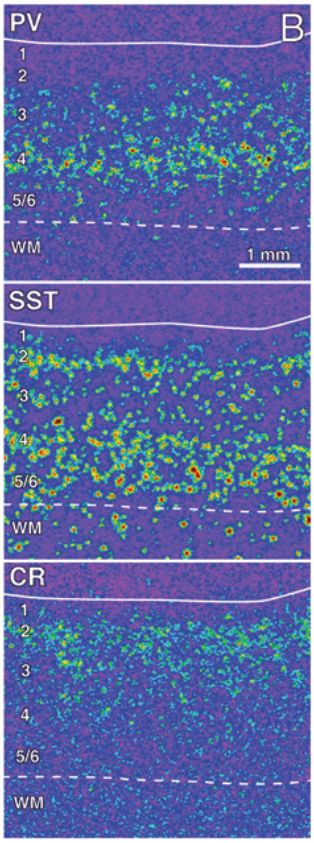
EXCITATORY AND INHIBITORY AMINO ACID NEUROTRANSMITTERS IN THE CONTEXT OF NEURAL CIRCUITRY



The amino acid neurotransmitters are the most abundant and widely used neurotransmitters in the brain. The excitatory neurotransmitter glutamate and the inhibitory neurotransmitter GABA are the predominant transmitters in both the local and long-range circuits that form distributed neural networks. In the brain, L-glutamate is synthesized in axon terminals from glucose (via the Krebs cycle) or from glutamine that is converted into glutamate by the enzyme glutaminase. The synaptic action of glutamate is terminated by the glutamate transporter, which is located on the presynaptic axon terminal. GABA is synthesized in the brain by the decarboxylation of L-glutamic acid, which is catalyzed by the enzyme glutamic acid decarboxylase. As in other neurotransmitter systems, the synaptic action of GABA is terminated by the GABA transporter. In the following section, we focus on the cell types and projections utilizing these two neurotransmitters in the neocortex, basal ganglia, and thalamus, given that these brain regions have been implicated in the pathophysiology of a number of psychiatric disorders.

Cerebral Cortex



Pyramidal cells, the predominant projection neurons of the cerebral cortex, utilize glutamate as their neurotransmitter. Most pyramidal neurons are characteristically shaped and possess a single apical dendrite that extends toward the pial surface. In addition, several basilar dendrites extend from the base of the cell body in a radial fashion. Dendritic spines, short extensions of the dendritic shafts, coat both apical and basilar dendrites. Pyramidal neurons have principal axons that enter the white matter and project to other cortical regions, as well as axon collaterals that travel either horizontally or vertically within the gray matter. In all cortical areas, pyramidal cells are located in layers 2–6, and the laminar location of a pyramidal cell often indicates its projection target. For example, cortically projecting pyramidal neurons are predominantly located in layer 3, whereas striatal- and thalamic-projecting cells reside in layers 5 and 6, respectively (DeFelipe and Farinas 1992).

Nonpyramidal neurons are the other major class of cortical neuron, and the majority (90%) of these neurons utilize GABA as their neurotransmitter. Also known as interneurons, the axons of cortical GABA cells arborize within the gray matter and thus do not project out of the cortical region in which they reside. As many as 12 different subtypes of GABA neurons can be found in the cortex, and these can be distinguished biochemically, electrophysiologically, and morphologically (Figure 4–8) (Fairen et al. 1984; Krimer et al. 2005; Lund and Lewis 1993). For example, subpopulations of GABA cells can be distinguished by the presence of certain neuropeptides or calcium-binding proteins (Condé et al. 1994; Gabbott and Bacon 1996). In addition, the organization of the axonal arbor and synaptic targets of the axon terminals differ greatly across these different subtypes (Lund and Lewis 1993). As depicted in Figure 4–8, the chandelier class of GABA cell expresses the calcium-binding protein parvalbumin (DeFelipe et al. 1989; Lund and Lewis 1993) and has axon terminals that are arrayed as distinct vertical structures, termed *cartridges* (Fairen and Valverde 1980; Goldman-Rakic and Brown 1982). These axon terminals form inhibitory or symmetric synapses exclusively with the axon initial segments of pyramidal cells (DeFelipe et al. 1985). Parvalbumin-containing basket neurons form symmetric synapses with the cell bodies and dendrites of pyramidal neurons (Melchitzky et al. 1999; Williams et al. 1992). Parvalbumin-containing neurons are predominantly located in layers 3 and 4. Martinotti cells contain somatostatin and form symmetric synapses with the tuft dendrites of pyramidal neurons (Kawaguchi and Kubota 1997; Wang et al. 2004) and, to a lesser extent, with the dendrites of GABA neurons (Melchitzky and Lewis 2008). Double bouquet neurons have radially oriented axonal arbors and contain either somatostatin and the calcium-binding protein calbindin (DeFelipe 1993) or the calcium-binding protein calretinin (Condé et al. 1994). The somatostatin- and calbindin-containing double bouquet cells form symmetric synapses with the distal dendritic shafts and spines of pyramidal neurons. By contrast, the calretinin-containing double bouquet cells form symmetric synapses predominantly with the dendritic shafts of other GABA neurons (Gonchar and Burkhalter 1999; Meskenaite 1997), although they also target distal dendritic shafts and spines of pyramidal neurons to a lesser extent (Melchitzky et al. 2005). Calretinin-containing Cajal-Retzius cells reside solely in layer 1 and target the tuft dendrites of pyramidal neurons. These subpopulations of GABA neurons have differing laminar patterns of distribution (see Figure 4–8). For example, in the prefrontal cortex, layers deep 3 and 4 have the majority of parvalbumin-containing neurons (Condé et al. 1994; Gabbott and Bacon 1996); layers 2, superficial 3, and 5 have the greatest density of somatostatin-containing neurons (Lewis et al. 1986); and layer 2 has the highest density of calretinin-containing cells (Condé et al. 1994; Gabbott and Bacon 1996).

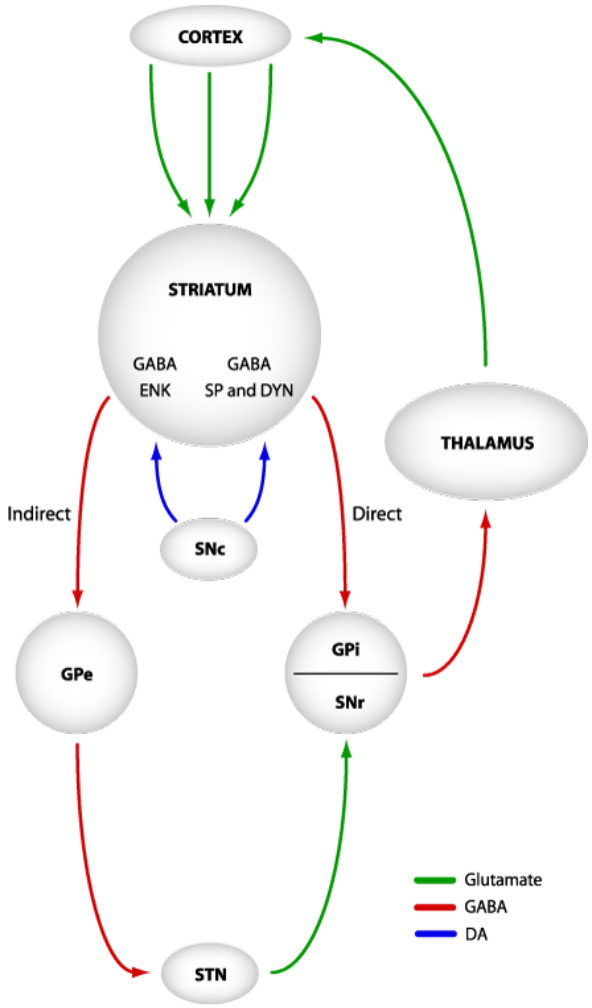
Multiple lines of evidence show that GABA neurons in monkey prefrontal cortex are involved in working memory tasks. For example, fast-spiking neurons are active during the delay period of working memory tasks (Wilson et al. 1994), and injection of GABA antagonists into the prefrontal cortex disrupts working memory (Sawaguchi et al. 1989). Patients with schizophrenia perform poorly on working memory tasks (Weinberger et al. 1986), and postmortem studies have demonstrated alterations in markers of GABA neurotransmission in the prefrontal cortex of schizophrenic subjects. For example, reduced mRNA for the 67 kiloDalton isoform of glutamic acid decarboxylase, the principal determinant of GABA synthesis, is one of the most consistent findings in postmortem studies of individuals with schizophrenia (Akbarian and Huang 2006). In addition, mRNA levels of parvalbumin and somatostatin, but not of calretinin, are reduced in the prefrontal cortex of subjects with schizophrenia (Hashimoto et al. 2003, 2008).

Thalamus

The dorsal thalamus is a heterogeneous structure composed of numerous nuclei that are distinguished on the basis of their location, cytoarchitecture, and connections with other brain regions. The projection or relay neurons within these nuclei use glutamate as their neurotransmitter and thus provide excitatory input to their target regions. For example, the axon terminals that project from the thalamus to primary sensory cortices contain glutamate immunoreactivity and form Gray's type I synapses (Kharazia and Weinberg 1994).



There are two groups of GABA-containing neurons in the primate thalamus: the interneurons, whose axons and actions are confined within the various dorsal thalamic nuclei, and the neurons of the reticular nucleus. All of the neurons in the reticular nucleus are GABAergic, and they provide extensive projections to the nuclei of the dorsal thalamus, the principal and possibly sole target of the reticular nucleus (Steriade et al. 1997). Thus, as in the cortex, the activity of the long-range excitatory projections from the thalamus is regulated by inhibitory inputs from nearby GABA neurons.

Basal Ganglia

The basal ganglia consist of the striatum (comprising the caudate nucleus, putamen, and nucleus accumbens), the globus pallidus (internal and external segments), and the substantia nigra pars reticulata. The internal segment of the globus pallidus and the substantia nigra pars reticulata are often grouped together and are referred to as the output nuclei of the basal ganglia. In contrast to the cortex and thalamus, the projection neurons of the basal ganglia utilize GABA as a neurotransmitter. For example, the GABA-containing medium spiny neurons of the striatum, which are the principal target of the excitatory projections from cortical pyramidal cells (Alexander and Crutcher 1990), project to the output nuclei of the basal ganglia (Figure 4–9). These medium spiny striatal neurons express substance P and dynorphin as well as GABA (Gerfen and Young 1988). The GABA projection neurons of the output nuclei of the basal ganglia project to the thalamus, where they form inhibitory contacts with thalamic projection neurons. This pathway from the striatum through the output nuclei of the basal ganglia to the thalamus is known as the "direct" pathway through the basal ganglia, and it results in disinhibition of the thalamus, which in turn sends a glutamatergic projection back to the cerebral cortex (Alexander and Crutcher 1990). In the "indirect" pathway (see Figure 4–9), GABA- and enkephalin-containing neurons in the striatum project to the external segment of the globus pallidus (Gerfen and Young 1988), where they target GABA projection neurons. The axons of these pallidal projection neurons target glutamate-containing cells in the subthalamic nucleus, which then project to GABA neurons of the output nuclei of the basal ganglia. Similar to the direct pathway, the output nuclei of the basal ganglia send GABAergic projections to the thalamus. In both the direct and indirect pathways, the cerebral cortex sends glutamatergic projections to the striatum and receives glutamatergic input from the thalamus, thus forming a corticostriatal circuit (see Figure 4–9). DA released from neurons in the substantia nigra pars compacta appears to

facilitate transmission through the direct pathway, via D_1 receptors on the substance P/dynorphin cells, and to inhibit transmission through the indirect pathway, via D_2 receptors on the enkephalin cells (Albin et al. 1989; Gerfen et al. 1990).

The nigrostriatal projection constitutes one of the major inputs to the basal ganglia. The striatum reciprocates and sends projections back to the midbrain DA neurons (Figure 4–10), forming a striatonigrostriatal circuit. The midbrain DA neurons can be divided into two tiers: the dorsal tier (which includes neurons of the dorsal substantia nigra pars compacta, the ventral tegmental area, and the retrorubral group) and the ventral tier (composed of the densocellular and cell column neurons of the substantia nigra pars compacta) (Haber and Fudge 1997). As illustrated in Figure 4–10, there is an inverse dorsal–ventral topographical organization to the projection from the dorsal and ventral DA neurons to the striatum (Haber 2003). For example, dorsally and medially located DA neurons project to the ventral and medial parts of the striatum (red and yellow pathways in Figure 4–10), whereas ventrally and laterally located DA neurons project to the dorsal and lateral parts of the striatum (green and blue pathways in Figure 4–10). Another prominent input to the striatum derives from the cerebral cortex, and this projection has a topographic organization related to that of the striatonigrostriatal pathway (see Figure 4–10). The orbital and medial prefrontal cortices project to the ventral striatum, the dorsolateral prefrontal cortex projects to the central striatum, and the premotor and motor cortices project to the dorsolateral striatum. These topographies create limbic, associative, and motor pathways (red/orange, yellow, and green/blue, respectively, in Figure 4–10) within the corticostriatalcortical and striatonigrostriatal projections.

NEUROPEPTIDES

Neuropeptides are generally thought to modulate the effects of classical neurotransmitters and are often collocated with neurotransmitters within neurons. This section focuses on six neuropeptides that have been implicated in the pathophysiology of psychiatric disorders.

Corticotropin-Releasing Factor

Corticotropin-releasing factor (CRF) is best known as a hormone that is secreted by the hypothalamus and that stimulates adrenocorticotropic hormone (ACTH) release from the pituitary, which results in the production of cortisol by the adrenal glands. Specifically, CRF is localized to neurons of the paraventricular nucleus in the hypothalamus, which send axons to the median eminence. CRF-containing cells are also localized to other hypothalamic nuclei, such as the medial preoptic area and the dorsomedial, arcuate, and mammillary nuclei (DeSouza and Grigoriadis 2002), as well as to the amygdala and bed nucleus of the stria terminalis (Keller et al. 2006). Besides the median eminence, CRF axons are present in the cerebral cortex, brain stem (including the locus coeruleus), and spinal cord. To date, two CRF receptors have been identified, CRF_1 and CRF_2. CRF_1 receptors are expressed in the pituitary, cerebral cortex, hippocampus, amygdala, and medial septum, and CRF_2 receptors are localized to the hypothalamic nuclei, lateral septum, and bed nucleus of the stria terminalis (Keller et al. 2006).

It has been hypothesized that hyperactivity of hypothalamic CRF might underlie the hypercortisolemia and contribute to the symptomatology seen in major depression (Aborelius et al. 1999). Furthermore, given that both NE and DA have been shown to be involved with stress as well as with depression, the presence of CRF-containing axons in NE- and DA-containing nuclei provides another mechanism by which CRF can affect stress responses (Austin et al. 1997).

CRF also appears to have effects on cognitive processing. Of interest, CRF is found in GABA-containing cells in the cerebral cortex, with the highest densities of these cells found in prefrontal, insular, and cingulate cortices (DeSouza and Grigoriadis 2002). In addition, cortical CRF has also been implicated in major depression and in Alzheimer's disease. For example, a decrease in CRF binding sites in the frontal cortex of suicide victims compared with normal controls has been demonstrated (Mitchell 1998). Furthermore, in postmortem tissue from individuals with Alzheimer's disease, CRF-containing axons are associated with amyloid deposits in the cerebral cortex (Powers et al. 1987); reduced CRF levels in frontal, temporal, and parietal cortices are correlated with the severity of dementia (Davis et al. 1999).

Neuropeptide Y

Neuropeptide Y (NPY) is a 36–amino acid peptide that, along with its receptors, is widely distributed within the central nervous system (Wettstein et al. 1995). The regions of the human brain that contain high densities of NPY-containing neurons include the striatum and amygdala, with the hypothalamus, cerebral cortex, hippocampus, periaqueductal gray, and basal forebrain having moderate levels of NPY-containing cells (Schwartzberg et al. 1990). Five G

protein–coupled NPY receptor subtypes, termed Y_1–Y_5, have been identified and cloned (Redrobe et al. 2002). The NPY receptors Y_1 and Y_2 are the most abundant and are found in the cerebral cortex, thalamus, brain stem, and hypothalamus (Redrobe et al. 2002). In addition to its role in regulating eating behavior, NPY has been implicated in affective disorders. For example, in a rodent model of depression, chronic antidepressant treatment increased NPY and Y_1 mRNA levels (Caberlotto et al. 1998). In humans, cerebrospinal fluid and plasma levels of NPY are lower in depressed patients than in controls (Nilsson et al. 1996; Westrin et al. 1999), and these levels increase after electroconvulsive therapy (Mathé et al. 1996). In addition, NPY mRNA is reduced in the prefrontal cortex of subjects with bipolar disorder (Caberlotto and Hurd 2001) and subjects with schizophrenia (Hashimoto et al. 2008).

Substance P

Substance P is a member of the family of neuropeptides known as the tachykinins, which also includes neurokinin A and B. The actions of these neuropeptides are mediated through the specific G protein–coupled receptors NK_1, NK_2, and NK_3, and substance P is the preferred agonist for the NK_1 receptor (Hökfelt et al. 2001). Substance P is found throughout the nervous system. In particular, substance P is expressed in brain regions that appear to be involved in emotion, such as the amygdala, periaqueductal gray, and hypothalamus (Pioro et al. 1990). In addition, substance P is collocated with serotonin in approximately 50% of the dorsal raphe neurons in the human brain (Baker et al. 1991; Sergeyev et al. 1999), and a large number of serotonin-containing dorsal raphe neurons express the NK_1 receptor (Lacoste et al. 2006).

Studies in animals have suggested that substance P, besides having a role in pain and inflammation, may also be involved in anxiety and in neurochemical responses to stress. For example, injection of substance P into periaqueductal gray matter produced anxiety-like behavior in rats (Aguiar and Brandao 1996). Furthermore, in guinea pigs subjected to maternal separation, the number of neurons with NK_1 receptor internalization increased in the basolateral amygdala (Kramer et al. 1998).

Substance P also appears to be involved in depression. For example, elevated concentrations of substance P have been reported in the cerebrospinal fluid of depressed patients (Rimon et al. 2002).

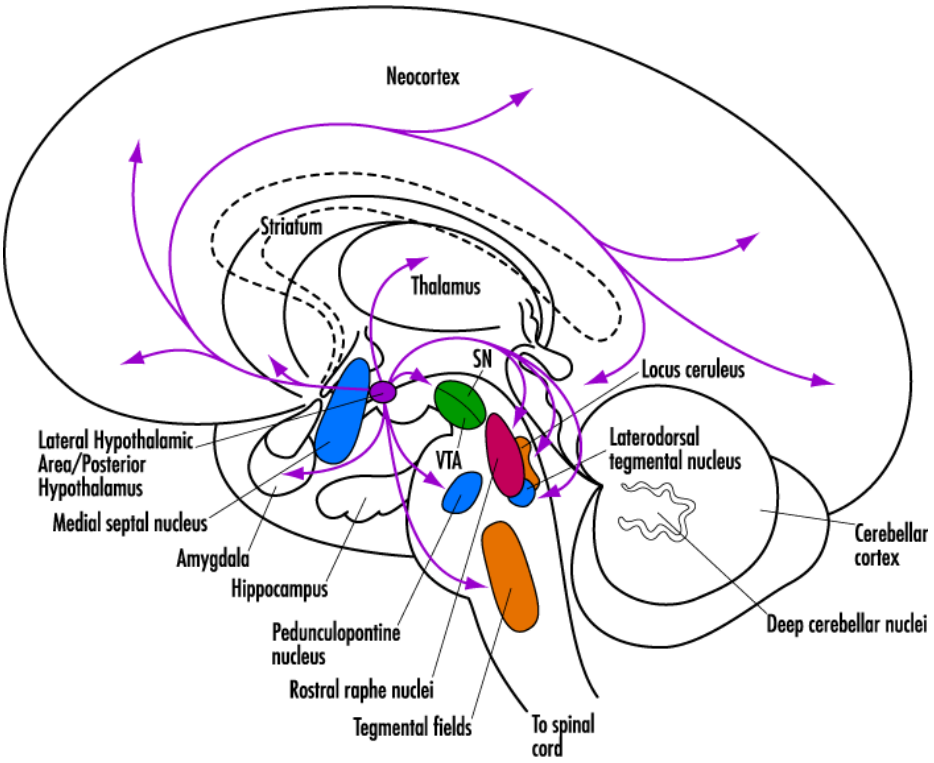
Neurotensin

Neurotensin is a tridecapeptide found throughout the brain, with high tissue concentrations in the amygdala, lateral septum, bed nucleus of the stria terminalis, substantia nigra, and ventral tegmental area (Caceda et al. 2006). Similarly, neurotensin-immunoreactive neurons are found in the amygdala, bed nucleus of the stria terminalis, lateral septum, and preoptic and lateral hypothalamus (Geisler et al. 2006). Three types of neurotensin receptors have been cloned, NTS_1–NTS_3, with NTS_1 and NTS_2 being G protein–coupled receptors and NTS_3 belonging to the vacuolar sorting receptor family (Caceda et al. 2006). High levels of mRNA for all three of these receptor types are found in the substantia nigra and amygdala.

Neurotensin has a strong association with the dopaminergic system, as evidenced by the heavy neurotensin innervation of nuclei that have high densities of DA cells or axons, such as the ventral tegmental area and the amygdala, respectively (Geisler et al. 2006). In addition, the majority of DA neurons in the ventral tegmental area express NTS_1 (Fassio et al. 2000), and neurotensin axons in this area arise from the preoptic and lateral hypothalamus (Zahm et al. 2001). Because of the role of DA in neuropsychiatric disorders such as schizophrenia, the localization and function of neurotensin in the brain have been widely studied. One of the most consistent findings is reduced cerebrospinal fluid concentrations of neurotensin in neuroleptic-naive people diagnosed with schizophrenia (Sharma et al. 1997). In addition, clinically effective antipsychotic drug treatment may increase cerebrospinal fluid neurotensin levels in schizophrenia (Sharma et al. 1997). Neurotensin has also been implicated in Parkinson's disease, which involves the progressive loss of DA neurons in the striatum. For example, decreases in neurotensin receptor binding as well as in NTS_1 receptor mRNA have been found in the substantia nigra and striatum of patients with Parkinson's disease (Yamada et al. 1995).

Somatostatin

The neuropeptide somatostatin was first identified in the hypothalamus as a tetradecapeptide (Brazeau et al. 1973). Other peptides of the somatostatin family, all of which are derived from the prosomatostatin protein, include somatostatin-28 and somatostatin-$28_{1–12}$ (Benoit et al. 1982). The hypothalamus and limbic regions such as the amygdala and hippocampus have large numbers of somatostatin-containing neurons. A small number of somatostatin neurons are localized to the cerebral cortex and are particularly abundant in layers 2–3 and layers 5–6 (Epelbaum et al. 1994). Somatostatin-containing neurons in the cerebral cortex have a nonpyramidal morphology and contain GABA (Hendry et al. 1984). The principal somatostatinergic tract projects from the anterior periventricular nucleus of the hypothalamus to the median eminence (Patel 1999). This projection inhibits secretion of growth hormone, thyroid-stimulating hormone, and prolactin from the adenohypophysis (Epelbaum et al. 1994). The actions of somatostatin are mediated by five distinct subtypes of G protein–coupled receptors, SST_1–SST_5. The SST_2 receptor undergoes alternative splicing that results in two forms, SST_{2A} and SST_{2B} (Epelbaum et al. 1994). Although all somatostatin receptors appear to be present in the brain (Patel 1999), the SST_2 receptor is the most widely studied. In rodent brain, the SST_{2A} receptor protein has been localized to the cerebral cortex, basal ganglia, and hippocampus (Dournaud et al. 1996; Hervieu and Emson 1998).



The widespread distribution of somatostatin cells and receptors reflects the varied physiological actions that somatostatin release has in the nervous system, ranging from thermoregulation to cognitive functions such as learning and memory (Epelbaum et al. 1994). Deficits in the somatostatin system in Alzheimer's disease are some of the most consistent findings in this neurodegenerative disease. Decreases in cerebrospinal fluid somatostatin levels, selective degeneration of cortical somatostatin neurons, and reduction in cortical somatostatin receptors have all been found in Alzheimer's disease (Bissette 1997).

Somatostatin has also been implicated in the pathophysiology of schizophrenia. For example, studies have revealed decreased expression of somatostatin mRNA in the prefrontal cortex of individuals with schizophrenia (Hashimoto et al. 2008), specifically in layers 2–6 (Morris et al. 2008).

Orexins

The orexin neuropeptides, orexin A and orexin B (also known as hypocretin A and hypocretin B), were identified in the late 1990s as endogenous ligands for two orphan G protein–coupled receptors (de Lecea et al. 1998; Sakurai et al. 1998). Orexin A and orexin B are derived from a single precursor gene, *prepro-orexin.* Because neurons in the lateral hypothalamic area, a region with an established role in feeding behavior, produce these neuropeptides, Sakurai et al. (1998) named them orexins, based on the Greek word for appetite, *orexis.* Neurons producing orexin are also located in posterior and perifornical hypothalamus. Estimates of the number of orexin neurons range from 3,000 in rat brain (Nambu et al. 1999) to 7,000 in human brain (Peyron et al. 1998). Orexin neurons project throughout the brain, with the exception of the cerebellum (Figure 4–11). Interestingly, orexin neurons project to most of the monoaminergic (substantia nigra, locus coeruleus, dorsal raphe) and cholinergic (medial septum, pedunculopontine, laterodorsal tegmental) nuclei (Sakurai 2007). Orexin neurons also have widespread projections throughout the cerebral cortex. Areas containing high densities of orexin axons include the paraventricular thalamic nucleus, the arcuate nucleus of the hypothalamus, the locus coeruleus, and the dorsal raphe nucleus (Nambu et al. 1999).

The multiple actions of orexin are mediated by two types of G protein–coupled receptors, orexin 1 and orexin 2, which display high homology. In concert with the widespread projections of orexin neurons, the orexin receptors are located throughout the brain (Marcus et al. 2001). For example, the mRNA for orexin 1 is found in the prefrontal cortex, the CA2 field of the hippocampus, the paraventricular thalamic nucleus, the ventromedial hypothalamic nucleus, and the locus coeruleus. The distribution of the mRNA for orexin 2 is somewhat complementary to that of orexin 1 in that it is found in the piriform cortex, CA3 field of the hippocampus, rhomboid thalamic nucleus, dorsomedial hypothalamic nucleus, and tuberomammillary nucleus (Marcus et al. 2001). Some regions of the brain, such as the raphe nuclei, ventral tegmental area, and substantia nigra, express both orexin receptors.

The location of orexin-containing neurons in the feeding center of the brain (lateral hypothalamic area) and the projections of orexin neurons to neuronal systems involved in sleep and wakefulness (locus coeruleus, raphe nuclei, and laterodorsal/pedunculopontine tegmental nuclei) and reward (ventral tegmental area) illustrate the variety of functions in which orexin neurons participate (Harris and Aston-Jones 2006). Supporting orexin's involvement in feeding behavior, administration of an anti-orexin antibody or an orexin 1 receptor antagonist to rats reduces food intake (Haynes et al. 2002; Yamada et al. 2000). Numerous studies in both animals and humans show that orexin deficiency is the main cause of narcolepsy. For example, mice that lack the orexin gene exhibit physiological symptoms similar to those of human narcolepsy (Chemelli et al. 1999). More direct evidence of orexin's role in narcolepsy is that postmortem examination of the brains of narcolepsy patients revealed an 85%–95% reduction in the number of orexin-immunoreactive neurons (Thannickal et al. 2000). A recent study of an orexin receptor antagonist demonstrated the usefulness of this drug in inducing sleep without cataplexy (Brisbare-Roch et al. 2007), providing hope to people who suffer from sleeping disorders like narcolepsy. Current treatments for narcolepsy include addictive amphetamine-like drugs, but patients taking these drugs rarely become addicted (Harris and Aston-Jones 2006). This finding has led to speculation that orexins may also be involved in reward processing and addiction. For example, orexin neurons activate ventral tegmental DA neurons, which, through their projections to the nucleus accumbens, form the "reward" pathway. In addition, in rodents, administration of orexin directly into the ventral tegmental area reinstates an extinguished drug preference (Harris et al. 2005).

CONCLUSION

This chapter reviews the basic framework of the anatomical distribution of the major neurochemical systems in the primate brain, including the anatomical determinants of where neurotransmitters are released and where they produce their effects. These organizational schema provide important constraints on the actions of the neurotransmitters and neuromodulators. In addition, the consequences of the cellular actions and of pharmacological manipulations of their synthesis, release, reuptake, and receptor binding depend on the rich and diverse interplay across these neurochemical systems. Clearly, a major challenge for the future involves the elucidation of these interactions and the characterization of how these interactions are disturbed in psychiatric disorders. Such information is critical for identification and validation of potential molecular targets for the rational development of new pharmacotherapies for psychiatric illnesses.

Chapter 5. Electrophysiology

ELECTROPHYSIOLOGY: INTRODUCTION

Several approaches can be used to analyze the structure and function of the nervous system in health and disease. Many of these techniques—for example, the biochemical analysis of neurotransmitter and metabolite levels, anatomical studies of axonal projection sites or neurotransmitter enzymes, and molecular biological studies of messenger levels and turnover—examine the nervous system at the level of groups or populations of neurons. In contrast, by its very nature, electrophysiology is oriented toward the physiological analysis of individual neurons. In this chapter, we describe preparations and techniques that are in a general sense applicable to many systems, with specific examples from the dopaminergic system to draw on our field of expertise.

The use of electrophysiological techniques for the analysis of neuronal physiology depends on the unique properties of the neuronal membrane. Like many other cell types, the neuron possesses an electrochemical gradient across its membrane. The electrochemical gradient itself is a product of two forces: 1) an electrical potential force derived from the voltage difference between the inside and the outside of the cell and 2) a chemical potential force resulting from the unequal distribution of ions across the membrane. Cells set up and maintain this electrochemical gradient because of the selective permeability of their membranes to particular ionic species. Thus, the membrane has a rather high degree of permeability to ions such as potassium but is relatively impermeable to ions such as sodium and calcium.

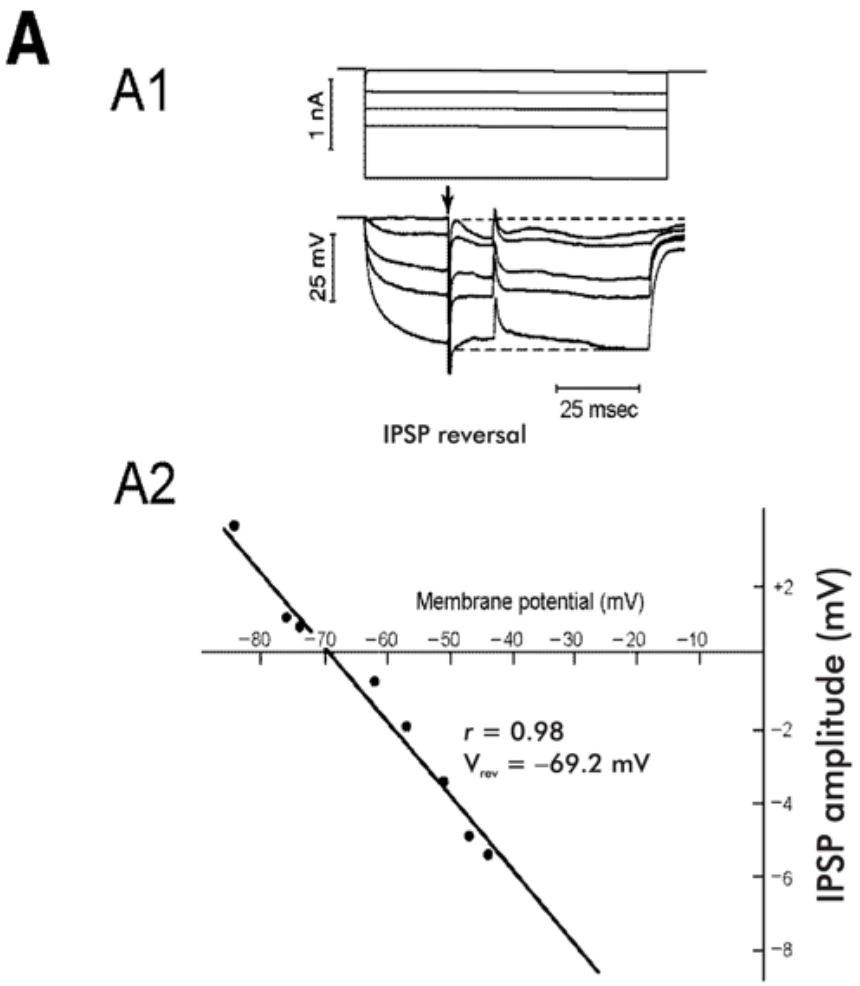
In the resting state, cells have a very low internal concentration of sodium and calcium. To achieve this state, the cell must expend energy (in the form of adenosine triphosphate [ATP] hydrolysis) to extrude sodium from the intracellular space in exchange for potassium ions. The extrusion of sodium sets up both a chemical gradient (because sodium attempts to exist in equal concentrations across the membrane) and an electrical gradient (because sodium is positively charged and is not freely permeable across the membrane; thus, net positive charges are being removed from inside the cell). To partially counter this electrical gradient, potassium—which is more permeable—flows down the electrical gradient to become concentrated inside the cell. However, during this process, the cell is also setting up an opposing chemical gradient, because potassium is achieving higher concentrations within the cell in comparison with the extracellular environment. When the electrical force drawing potassium into the cell balances the chemical force of the concentration gradient forcing potassium out of the cell, the membrane is at equilibrium—with high extracellular sodium concentrations, relatively high intracellular potassium concentrations, and a transmembrane potential causing the inside of the cell to be negatively charged with respect to its environment.

A typical resting membrane potential for a neuron is rather small, being on the order of –70 mV with respect to the extracellular fluid. In actuality, potassium itself is not freely permeable. A small electrochemical gradient exists in most neurons that attempts to force potassium out of the cell and draw the membrane potential to more negative values. Although the scenario is somewhat more complicated than this (e.g., involving charged proteins and other ionic species with selective permeabilities), this description approximates how a cell gains an electrochemical gradient via the energy-dependent extrusion of sodium.

Note that neurons are not the only cells that have transmembrane potentials. In fact, all living cells have an electrochemical gradient across their membranes that they use for transporting glucose and other essential materials and accumulating them against a concentration gradient. Such energy-dependent processes are usually coupled to other gradients from which they derive this energy. For example, a compound may be taken up and concentrated by linking its transport to sodium, which itself has a large electrochemical gradient in the opposite direction. What makes the neuron unique is its ability to rapidly change the permeability of its membrane to one or more ion species in a regenerative manner. This process underlies the generation of an action potential, sets up active propagation of an action potential down an axon, and triggers the procedure that ultimately results in neurotransmitter release. It also provides the electrophysiologist with a measure of neuronal activity that can be assayed by recording the electrical activity generated by the neuron.

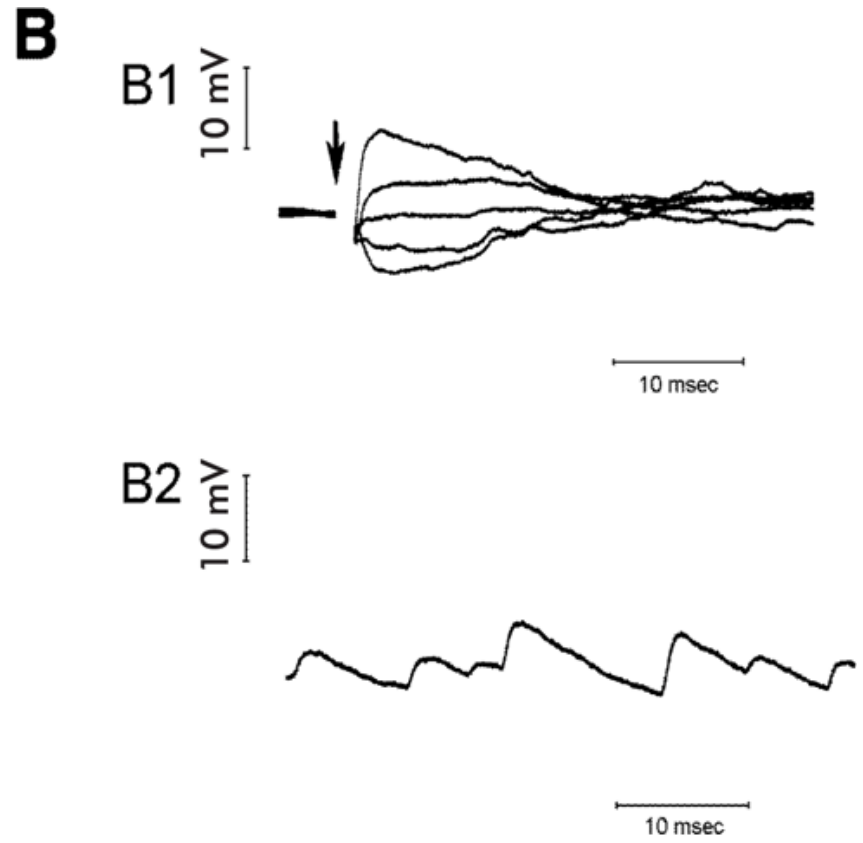
The *action potential* is an active regenerative phenomenon, which means that the events that initiate the action potential also serve as the force that drives this event to completion. Normally, a given neuron receives information in the form of synaptic potentials. For example, an axon terminal synapsing on the neuron releases a neurotransmitter, which binds to the neuron and selectively alters the permeability of its membrane by opening ion channels linked to its

binding site. An ion channel that opens in response to a neurotransmitter is referred to as a *ligand-gated channel*. If the neurotransmitter activates a channel that increases the permeability of the membrane to a negatively charged ion present in high concentrations in the extracellular fluid (e.g., chloride), the influx of chloride down its electrochemical gradient causes a negative shift in the membrane potential of the cell, thereby increasing the potential difference across the membrane, or a hyperpolarization of the cell. If activation of this channel causes a positively charged ion such as sodium to flow down its electrochemical gradient and into the cell, it will cause a brief decrease in the membrane potential (i.e., a depolarization) of the neuron.



Because a change in the membrane potential alters the electrochemical gradient of potassium across the membrane, potassium ions will flow through their respective channels to restore the membrane to its resting level. Thus, a neurotransmitter that depolarizes the membrane causes an efflux of potassium ions and a return of the membrane potential to resting levels. However, if the depolarization is large enough, another type of channel is activated—the *voltage-gated* or *voltage-dependent sodium channel*. In response to a given level of depolarization, this channel increases its permeability to sodium to allow more of this ion to enter the cell. The result is a further depolarization of the membrane and consequently an increased activation of this voltage-dependent channel. Because of the positive-feedback nature of this event, it is referred to as *regenerative,* because the depolarization augments the very factor that causes the cell to be depolarized. The membrane potential at which this regenerative process is initiated is thus the threshold potential for action potential generation, with a hyperpolarization of the cell causing a decrease in its excitability and a depolarization increasing the likelihood that it will generate an action potential.

The regenerative depolarization of the membrane has limits, however. One limit is the equilibrium potential for sodium. The *equilibrium potential* is the membrane potential at which the electrochemical gradient for a particular ion is zero, with no net flux of the ion across a membrane. This would occur when the membrane potential is sufficiently positive to oppose the further influx of the positively charged sodium ion across its concentration gradient. Although this potential is usually about +40 mV in many cells, the action potential does not actually reach this value. Instead, another voltage-activated channel that is selectively permeable to potassium is activated. The resultant massive increase in potassium permeability starts to return the membrane potential to its original state, thereby inactivating the regenerative sodium conductance. The increased potassium permeability is sufficient to drive the membrane potential negative to the resting potential and toward the equilibrium potential for potassium (i.e., approximately –80 to –90 mV) before the subsequent decrease in voltage-dependent potassium conductance returns the membrane to its original resting state.



The equilibrium potential of an ion determines the net effect that opening its associated ion channels will have on the neuron. The equilibrium potential occurs when the membrane is depolarized or hyperpolarized sufficiently to offset exactly the effects of the concentration gradient on the ion; as a result, no net flux of this ion crosses the membrane. For example, because of the very high concentration of sodium outside the neuron compared with inside the cell, the large concentration gradient for sodium across the membrane attempts to force sodium into the neuron. Therefore, to oppose this concentration gradient, the membrane potential of the neuron would have to be highly positive to provide an electrical gradient of equivalent force. This occurs at approximately +40 mV for sodium. However, potassium's equilibrium potential is about 10–20 mV more negative than its resting potential, which is partly the result of ATP hydrolysis that exchanges extruded sodium for potassium. As a result, increasing potassium permeability causes a hyperpolarization of the neuron because of an efflux of potassium down its concentration gradient.

Chloride is another common ionic species. This ion is negatively charged and therefore has an electrical gradient that would act against its entering the cell. However, the concentration of chloride is so much higher in the extracellular fluid that the chemical gradient predominates. As a result, opening chloride ion channels causes chloride to flow into the cell, hyperpolarizing the membrane (Figure 5–1). In fact, the opening of chloride ion channels is the mechanism through which the primary inhibitory neurotransmitter in the brain (i.e., γ-aminobutyric acid [GABA]) decreases neuronal activity.

At least three techniques can be used to determine the ionic species that mediates a synaptic response: determining the reversal potential of the ion, reversing the membrane potential deflection produced by changing the concentration gradient of the ion across the membrane, and determining the reversal potential (or blocking the synaptic response) after applying a specific ion channel blocker. In this figure, three techniques are used to illustrate the involvement of a chloride ion conductance increase evoked in dopamine-containing neurons by stimulation of the striatonigral γ-aminobutyric acid (GABA)ergic projection. **(A)** The reversal potential of a response may be determined by examining the amplitude of the response as the membrane potential of the neuron is varied. In this example, we superimposed several responses of the neuron evoked at increasingly hyperpolarized membrane potentials *(top traces),* with the membrane potential altered by injecting current through the electrode and into the neuron *(bottom traces = current injection).* **(A1)** A synaptic response in the form of an inhibitory postsynaptic potential (IPSP) is evoked in a dopamine neuron by stimulating the GABAergic striatonigral pathway *(arrow).* When increasing amplitudes of hyperpolarizing

current *(lower traces)* are injected into the neuron through the electrode, a progressive hyperpolarization of the membrane occurs *(top traces).* As the membrane is made more negative, the IPSP diminishes in amplitude, eventually being replaced by a depolarizing response. **(A2)** Plotting the amplitude of the evoked response *(y-axis)* against the membrane potential at which it was evoked *(x-axis)* illustrates how the synaptic response changes with membrane potential. The membrane voltage at which the synaptic response is equal to zero (i.e., ~69.2 mV in this case) is the reversal potential of the ion mediating the synaptic response (i.e., the potential at which the electrochemical forces working on the ion are zero). Therefore, there is no net flux of ions that cross the membrane. At more negative membrane potentials, the flow of the ion is reversed, causing the chloride ion (in this case) to exit the cell and result in a depolarization of the membrane. **(B)** The flow of an ion across a membrane may also be altered by changing the concentration gradient of the ion across the membrane. Normally, chloride ions flow from the outside of the neuron (where they are present at a higher concentration) to the inside of the neuron (where their concentration is lower), causing the membrane potential to become more negative. In this case, the concentration of chloride ions across the membrane of the dopamine neuron is reversed by using potassium chloride as the electrolyte in the intracellular recording electrode. **(B1)** Soon after the neuron is impaled with the potassium chloride–containing electrode, stimulation of the striatonigral pathway *(arrow)* evokes an IPSP *(bottom trace).* However, as the recording is maintained, chloride is diffusing from the electrode into the neuron, causing the electrochemical gradient to decrease progressively over time. As a result, each subsequent stimulation pulse evokes a smaller IPSP, eventually causing the IPSP to reverse to a depolarization *(top trace).* The depolarization is caused by an efflux of chloride ions out of the neuron and down its new electrochemical gradient. This has caused the reversal potential of the chloride-mediated response to change from a potential that was negative to the resting potential to one that is now positive to the resting potential. **(B2)** After injecting chloride ions into the neuron, spontaneously occurring IPSPs that were not readily observed in the control case are now readily seen as reversed IPSPs (i.e., depolarizations) occurring in this dopamine neuron recorded in vivo. **(C)** Another means for determining the ionic conductance involved in a response is by using a specific ion channel blocker. This can be done in two ways: by using the drug to block an evoked response or (as shown in this example) by examining the effects of administering the drug on the neuron to determine whether the cell is receiving synaptic events that alter the conductance of the membrane to this ion. To do this, the current–voltage relationship of the cell is first established. This is done by injecting hyperpolarizing current pulses into the neuron *(x-axis)* and recording the membrane potential that is present during the current injection *(y-axis).* These values are then plotted on the graph *(filled circles),* with the resting membrane potential being the membrane potential at which no current is being injected into the neuron *(y-intercept).* The slope of the resultant regression line *(solid line)* is equal to the input resistance of the neuron (Rinput = 36 megohms). After administration of the chloride ion channel blocker picrotoxin *(open boxes),* a new current–voltage relationship is established in a similar manner. Picrotoxin caused a depolarization of the membrane (y-intercept of dashed line is more positive) and an increase in the neuron input resistance (the slope of the dashed line is larger). The intersection of the membrane current–voltage plots obtained before and after picrotoxin administration is then calculated. By definition, this point of intersection (i.e., ~75 mV) is the reversal potential of the response to picrotoxin, because a neuron at this membrane potential would show no net change in membrane potential on drug administration.

Neurons within the vertebrate nervous system have additional conductances that provide them with unique functions. One of these conductances is the voltage-gated calcium conductance. Like sodium, calcium exists in higher concentrations outside the neuron compared with inside the cell. However, the gradient is even more extreme than it is for sodium. Even though much less calcium than sodium is present in the extracellular fluid, the equilibrium potential for calcium is almost +240 mV because of the extremely low intracellular concentration of this ion. The neuron maintains this low intracellular concentration so as to use this ion for specialized purposes. Thus, calcium influx causes neurotransmitter release, activates calcium-gated ion channels, and triggers second-messenger systems (e.g., calcium-regulated protein kinase). Calcium channels, like their sodium counterparts, are also voltage gated and cause calcium influx into the neuron during the action potential. Furthermore, calcium can influence the excitability of the cell by activating the calcium-activated potassium current, which then causes a large membrane hyperpolarization after the spike, known as an *afterhyperpolarization*, that delays the occurrence of a subsequent spike in that neuron. After entering the neuron, calcium is rapidly sequestered into intracellular organelles to terminate its action and reset the neuron before the next event. Therefore, calcium can alter the physiological activity and the biochemical properties of the neuron it affects (Llinás 1988).

In addition to the role of ion channels in setting the resting membrane potential, generating the action potential, and repolarizing the membrane potential, they can have a more subtle effect on aspects of electrophysiological function. For example, by regulating properties of the neuronal membrane, such as the amplitude and speed of the neuronal voltage response to inputs, ion channels can regulate neuronal responses to synaptic inputs. By modulation of these parameters, ion channels influence the integration of multiple synapses (temporal and spatial integration) and ultimately regulate the ability of synaptic inputs to depolarize membrane potentials and drive the generation of action potentials. Furthermore, neurotransmitters such as acetylcholine and monoamines can influence these same

parameters through modulation of ion channels.

ELECTROPHYSIOLOGICAL TECHNIQUES

Through use of a broad range of electrophysiological techniques to assess information about a neuron, such as those described earlier in this chapter, experiments can be designed to investigate differences in the physiological properties of neurons of interest, the interaction between neurotransmitter systems involved in behavioral or pathological conditions, and the mode of action of pathomimetic or psychotherapeutic agents. In attempting to gain such information, it is important to note that there is no "best" technique. Each approach has its relative strengths and weaknesses, and only through integrating information gained at these various levels will a more complete comprehension of neuronal function be achieved.

Numerous parameters of neuronal activity can be assessed electrophysiologically. These parameters can be selectively assessed depending on the method of recording used. Six recording methods are reviewed here: electroencephalographic (EEG) recordings, field potential recordings, single-unit extracellular recordings, intracellular recordings, patch clamp recordings, and whole-cell recordings. Which parameter is measured is essentially a function of the type of electrode used.

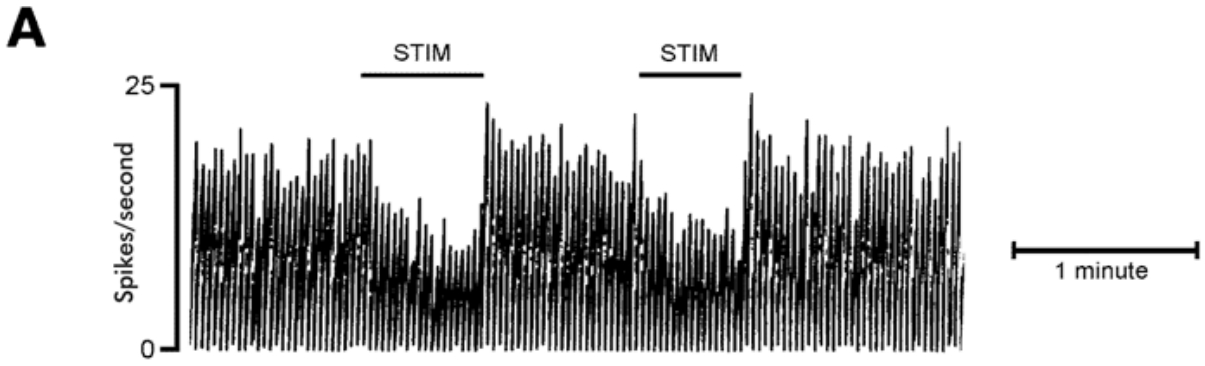
Electroencephalographic Recordings

In recording EEGs, the desired signal is very small in amplitude; thus, a large electrode that sums activity over large regions of the brain surface is used. Although this technique is less invasive than others, the information it yields is comparatively narrow, in that a large array of neurons must be simultaneously activated for the potentials to be recorded at the scalp. As a result, stimulus presentation and EEG averaging are typically required to separate the signal desired from the background noise.

Field Potential Recordings

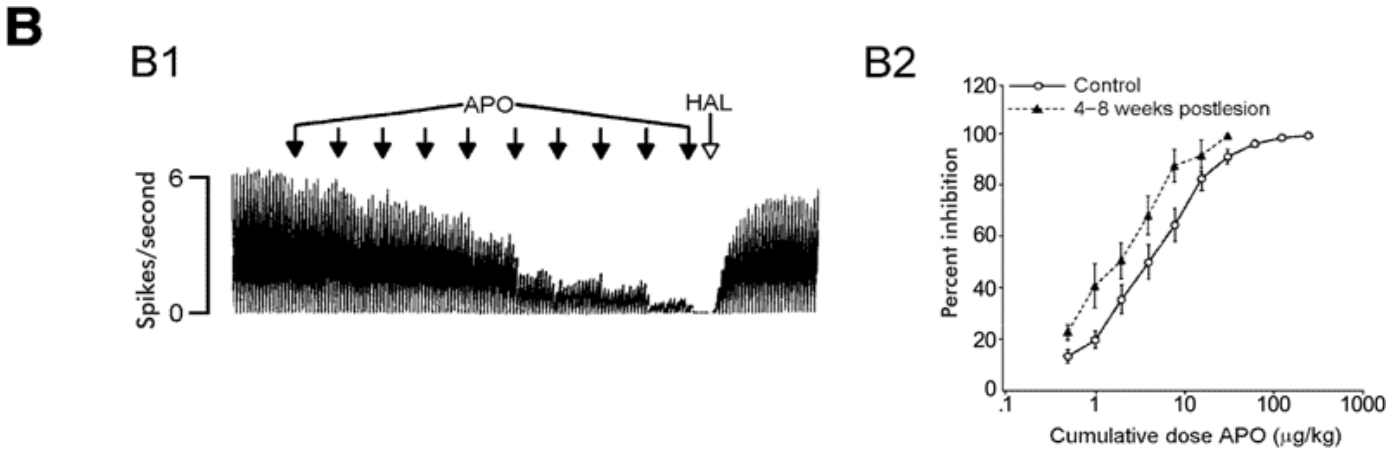
The next level of analysis is the recording of field potentials. This method uses a recording electrode with a smaller tip and a higher resistance than that for EEG electrodes, and the electrophysiological measures are confined to a small population of neurons surrounding the electrode tip. This technique still depends on the simultaneous activation of a number of cells; however, because the electrode is inserted into the brain, the cells do not have to be at the surface of the skull as in the EEG recordings. Furthermore, the activation can consist of stimulation of an afferent pathway. Nonetheless, the array of neurons sampled must have a common orientation for the massed activity to be measurable. Therefore, such measures are typically restricted to cortical structures such as the neocortex and hippocampus. With this method, the current resulting from the parallel activation of excitatory and inhibitory afferents can be measured as well as the electrophysiological response of a population of neurons to such stimulation.

On the other hand, even in structures without a parallel orientation of neurons, field recordings have been useful in evaluating changes in afferent synaptic strength. For example, field recordings have been particularly effective in examining phenomena manifesting synaptic plasticity, such as long-term potentiation. By measuring the fields generated by stimulating afferent inputs, one can evaluate how effective synaptic pathways are in driving a region and how this effectiveness can be modified by experience. Therefore, learning paradigms, behavioral conditioning, and drug sensitization have all been shown to alter evoked field potentials within functional pathways in the brain (e.g., Goto and Grace 2005b).



Single-Unit Extracellular Recordings

The next level of recording involves examining the electrophysiology of individual neurons with extracellular single-unit recording techniques. This technique requires that an electrode be placed in close proximity to a single neuron to record its spike discharge. An electrode with a smaller tip and a higher resistance than those used for recording field potentials results in the sampling of a smaller volume of tissue (i.e., the somata of individual neurons). Because the region sampled by the electrode is small, the signal is larger in amplitude and the background noise is less. This allows easy recording of the spontaneous spike discharge of a single neuron within the brain of a living (but typically anesthetized) animal. The cells examined are located through use of an atlas and a stereotaxic apparatus. The stereotaxic apparatus holds the head of the animal in a precise orientation so that a brain atlas may be used to place the recording electrodes accurately within the region of the brain desired. Furthermore, if a dye is dissolved in the electrolyte within the recording pipette, the dye may be ejected into the recording site for subsequent histological verification of the region recorded.



Because the recording electrode is placed near the outside surface of the neuron, there is less of a concern that the activity recorded is a result of damage to the neuron itself, as may be the case with intracellular recording techniques. Furthermore, many neurons may be sampled in a given animal. However, as a consequence, the amount of information that can be obtained from a neuron is limited. Typically, the research is relegated to recording information related to

action potential firing (e.g., the firing rate of the neuron, its pattern of spike discharge, and how these states of activity may be affected by stimulation of an afferent pathway or administration of a drug [Figure 5–2]). Nonetheless, when combined with the appropriate pharmacological techniques, extracellular recording has yielded a substantial amount of valuable information related to drug action or neuronal interconnections of physiologically important neuronal types. For example, by using a series of coordinated pharmacological and physiological techniques, we were able to define a unique extracellular waveform as that associated with the discharge of a dopamine-containing neuron (Bunney et al. 1973; Grace and Bunney 1983). This provided the basis for studies that yielded information defining the mode of action of antipsychotic drugs (Bunney and Grace 1978; Grace 1992).

Extracellular recording techniques are an effective means of assessing the effects of afferent pathway stimulation or drug administration on neuron activity. On the other hand, the measurements that can be made are typically restricted to changes in firing rates or in the pattern of spike discharge. **(A)** This firing rate histogram illustrates the response of a substantia nigra–zona reticulata neuron to stimulation of the γ-aminobutyric acid (GABA)ergic striatonigral pathway. A common method for illustrating how a manipulation affects the firing rate of a neuron is by constructing a firing rate histogram. This is typically done by using some type of electronic discriminator and counter to count the number of spikes that a cell fires in a given time. In this example, the counter counts spikes over a 10-second interval and converts this number to a voltage, which is then plotted on a chart recorder. The counter then resets to zero and begins counting spikes over the next 10-second interval. Therefore, in this firing rate histogram, the height of each vertical line is proportional to the number of spikes that the cell fires during each 10-second interval, with the calibration bar on the left showing the equivalent firing frequency in spikes per second. During the period at which the striatonigral pathway is stimulated *(horizontal bars above trace marked "STIM"),* the cell is inhibited, as reflected by the decrease in the height of the vertical lines. When the stimulation is terminated, a rebound activation of cell firing is observed. **(B)** In this figure, a similar histogram is used to illustrate the effects of a drug on the firing of a neuron. **(B1)** This figure shows the well-known inhibition of dopamine neuron firing rate on administration of the dopamine agonist apomorphine (APO). Each of the filled arrows represents the intravenous administration of a dose of APO. After the cell is completely inhibited, the specificity of the response is tested by examining the ability of the dopamine antagonist haloperidol (HAL *[open arrow]*) to reverse this response. Typically, drug sensitivity is determined by administering the drug in a dose–response fashion. This is done by giving an initial drug dose that is subthreshold for altering the firing rate of the cell. The first dose is then repeated, with each subsequent dose given being twice that of the previous dose. This is continued until a plateau response is achieved (in this case, a complete inhibition of cell discharge). **(B2)** The drug is administered in a dose–response manner to facilitate the plotting of a cumulative dose–response curve, with drug doses plotted on a logarithmic scale (i.e., a log dose–response curve). To compare the potency of two drugs or the sensitivity of two cells to the same drug, a point on the curve is chosen during which the fastest rate of change of the response is obtained. The point usually chosen is that at which the drug dose administered causes 50% of the maximal change obtained (i.e., the ED_{50}). As is shown in this example, the dopamine neurons recorded after a partial dopamine depletion *(dashed line)* are substantially more sensitive to inhibition by APO than the dopamine neurons recorded in control *(solid line)* rats. **(C)** In addition to determining the firing rate of a neuron, extracellular recording techniques may be used to assess the effects of drugs on the pattern of spike discharge. This is typically done by plotting an interspike interval histogram. In this paradigm, a computer is connected to a spike discriminator, and a train of about 500 spikes is analyzed. The computer is used to time the delay between subsequent spikes in the train (i.e., the time interval between spikes) and plots this in the form of a histogram, in which the x-axis represents time between subsequent spikes and the y-axis shows the number of interspike intervals that had a specific delay (bin = range of time; e.g., for 1-msec bins, all intervals between 200.0 and 200.99 msec). **(C1)** The cell is firing irregularly (as shown by the primarily normal distribution of intervals around 200 msec), with some spikes occurring after longer-than-average delays (i.e., bins greater than 400 msec, probably caused by spontaneous inhibitory postsynaptic potentials [IPSPs] delaying spike occurrence). **(C2)** In contrast, this cell is firing in bursts, which consist of a series of 3–10 spikes with comparatively short interspike intervals (i.e., approximately 70 msec) separated by long delays between bursts (i.e., events occurring at greater than 150-msec intervals). The computer determined that

in this case, the cell was discharging 79% of its spikes in bursts, compared with 0% in *(C1)*.

Extracellular recordings from neurons measure the current flow generated around a neuron as it generates spikes. For this reason, extracellular action potentials generally are composed of two components: a positive-going component followed by a negative-going component. The positive-going component is a reflection of the ion flux across the neuronal membrane surrounding the electrode that occurs during the depolarizing phase of the action potential, with the negative phase reflecting the repolarization. Because the extracellular recording electrode is measuring current across the membrane occurring in concert with changes in intracellular membrane potential and because current is defined in terms of the first derivative (i.e., rate of change) of voltage, the extracellularly recorded action potential (or spike) waveform is typically a first derivative of the action potential voltage with respect to time (Terzuolo and Araki 1961). This phenomenon underlies the biphasic nature of the extracellularly recorded event (Figure 5–3). Furthermore, the recorded spike is largest when the recording electrode is placed near the active site of spike generation because the current density is greatest (and thus the voltage drop induced across the electrode largest) at this site.

(A) During intracellular recordings, an action potential is initiated from a negative resting membrane potential (e.g., ~55 mV), reaches a peak membrane potential *(solid arrow),* and is followed by a repolarization of the membrane and usually an afterhyperpolarization. An inflection in the rising phase of the spike *(open arrow)* is often observed. This reflects the delay between the initial segment spike that initiates the action potential (occurring prior to the open arrow) and the somatodendritic action potential that it triggers (occurring after the open arrow). **(B)** A computer was used to differentiate the membrane voltage deflection occurring in the action potential in *(A)* with respect to time, resulting in a pattern that shows the rate of change of membrane voltage. Note that the inflection is exaggerated *(open arrow),* and the peak of the action potential crosses zero *(solid arrow),* because at the peak of a spike, the rate of change reaches zero before reversing to a negative direction. **(C)** A trace showing a typical action potential in a dopamine neuron recorded extracellularly. The extracellular action potential resembles the differentiated intracellular action potential in *(B).* This is because the extracellular electrode is actually measuring the current crossing the membrane during the action potential and is therefore, by definition, equivalent to the absolute value of the first derivative of the voltage trace in *(A).* The amplitude of the extracellular spike is indicated in volts, because the parameter measured is actually the voltage drop produced across the electrode tip by the current flux and is therefore much smaller than the actual membrane voltage change that occurs in *(A).*

Intracellular Recordings

With intracellular recording, an electrode with a much smaller tip and a much higher electrical resistance than that used with extracellular recording is inserted into the membrane of the neuron. Although the tip of the electrode is smaller, the signal measured is much larger than that with extracellular recording, because it measures the potential difference across the membrane directly rather than relying on transmembrane current density changes outside the neuron. As a result, one can measure electrical activity occurring within the neuron that would be nearly impossible to measure extracellularly, such as spontaneously occurring or evoked (via afferent pathway stimulation) electrical potentials generated by neurotransmitter release (or postsynaptic potentials). Furthermore, because the membrane potential of the neuron may be altered by injecting depolarizing or hyperpolarizing current into the cell through the electrode, the equilibrium potential (also known as the reversal potential) of the response may be determined. In addition, the overall conductance of the membrane may be measured by injecting known levels of current and measuring the membrane voltage deflection produced. By applying this information using Ohm's law, the input resistance of the cell can be determined. This could be important in assessing drug effects. A drug could increase the input resistance of the membrane, making it more responsive to current generated by afferent synapses, without changing the membrane potential of the neuron. Indeed, such a condition has been proposed to underlie the mechanism through which norepinephrine exerts a "modulatory" action—that is, increasing the amplitude of the response of a neuron to a stimulus without affecting its basal firing rate (which has also been described as increasing its "signal-to-noise" ratio; Freedman et al. 1977; Woodward et al. 1979).

The intracellular recording electrode can also be used to inject specific substances into the neuron. For example, second messengers or calcium chelators can be introduced into the neuron to examine how they regulate the excitability and modulate the baseline activity of the neuron or how they affect the neuron's response to drugs (Figure

5–4). Furthermore, by injecting the neuron with a fluorescent dye or enzymatic marker, the morphology of the specific cell impaled may be recovered and examined (Figure 5–5). This technique can be combined with immunocytochemistry to examine the neurotransmitter synthesized by the cell under study (e.g., Grace and Onn 1989).

Intracellular application of selective pharmacological agents enables the investigator to examine the direct effects of these agents on the membrane activity of single neurons as well as to manipulate intracellular second-messenger systems. This figure demonstrates that manipulation of intracellular cyclic guanosine monophosphate (cGMP) levels potently and specifically modulates the membrane activity of striatal medium spiny neurons in a manner that cannot be achieved by extracellular application of drugs. Striatal neurons were recorded after intracellular application (~5 minutes) of either A) vehicle (control), a 0.5% solution of dimethylsulfoxide (DMSO); B) the drug 1*H*-[1,2,4]oxadiazole[4,3-a]quinoxalin-1-one (ODQ), which blocks cGMP synthesis by inhibiting the synthetic enzyme guanylyl cyclase; C) ODQ plus cGMP; or D) the drug zaprinast, which inhibits phosphodiesterase enzymes responsible for degrading cGMP. **(A)** *Left:* After vehicle injection, striatal neurons exhibited typical rapid spontaneous shifts in steady-state membrane potential and irregular spontaneous spike discharge. *Right:* Time interval plots of membrane potential activity recorded

from control neurons demonstrated bimodal membrane potential distributions indicative of bistable membrane activity. **(B)** *Left:* Striatal neurons recorded after ODQ injection exhibited significantly lower-amplitude depolarizing events compared with vehicle-injected controls and rarely fired action potentials. *Right:* The depolarized portion of the membrane potential distribution of neurons recorded after ODQ injection was typically shifted leftward (i.e., hyperpolarized) compared with controls. **(C)** *Left:* Striatal neurons recorded after ODQ and cGMP coinjection rarely fired action potentials but exhibited high-amplitude depolarizing events with extraordinarily long durations. *Right:* The membrane potential distribution of neurons recorded after ODQ and cGMP coinjection was similar to that of controls, indicating that cGMP partially reversed some of the effects of ODQ. **(D)** *Left:* Striatal neurons recorded after intracellular injection of zaprinast exhibited high-amplitude depolarizing events with extraordinarily long durations. Additionally, all of the cells fired action potentials at relatively high rates (0.4–2.2 Hz). *Right:* The membrane potential distribution of these neurons was typically shifted rightward (i.e., depolarized) compared with controls. Because zaprinast blocks the degradation of endogenous cGMP, we can conclude that basal levels of cGMP depolarize the membrane potential of striatal neurons and facilitate spontaneous postsynaptic potentials. *Arrows* indicate the membrane potential at its maximal depolarized and hyperpolarized levels.

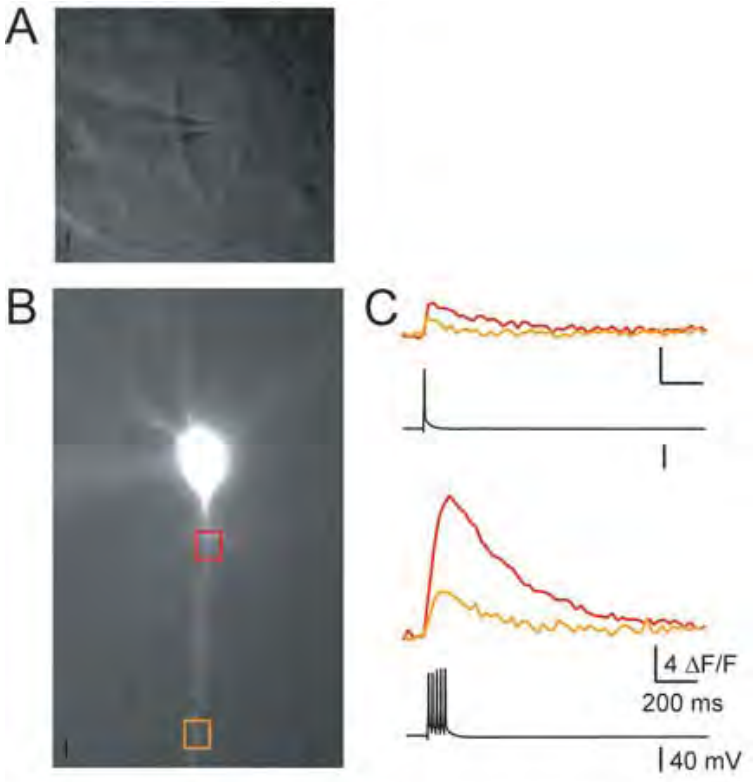
During intracellular recordings, the recording pipette is filled with an electrolyte to enable the transmission of membrane voltage deflections to the preamplifier. The electrode may also be filled with substances, such as a morphological stain, for injection into the impaled neuron. In this example, the electrode was filled with the highly fluorescent dye Lucifer yellow. Because this dye has a negative charge at neutral pH, it may be ejected from the electrode by applying a negative current across the electrode, with the result that the Lucifer yellow carries the negative current flow from the electrode and into the neuron. Because this dye diffuses rapidly in water, it quickly fills the entire neuron impaled. The tissue is then fixed in a formaldehyde compound, the lipids clarified by dehydration-defatting or by using dimethylsulfoxide (Grace and Llinás 1985), and the tissue examined under a fluorescence microscope. In this case, a brightly fluorescing pyramidal neuron in layer 3 of the neocortex of a guinea pig is recovered.

Inserting an electrode into the membrane of a cell to measure transmembrane voltage and manipulating its membrane by injecting current are commonly known as *current clamp,* because the amount and direction of ionic current crossing the membrane of the cell can be controlled by the experimenter, such as when determining the reversal potential of a response. Another technique that is effective in neurophysiological research is the use of *voltage clamping*. With

voltage clamping, the membrane potential of the neuron is maintained at a set voltage level by injecting current into the cell. This is achieved by rapid feedback electronics that adjusts the current injected to accurately offset any factors that may act to change this potential. Thus, when the neuron is exposed to a drug that opens ion channels, the effect of the ionic influx is precisely counterbalanced by altering the current injected into the neuron by the voltage clamp device. The amount of additional current that must be injected into the neuron to maintain the membrane potential at its set point is therefore the inverse of the transmembrane current generated in response to the drug. By using specific ion channel blockers or by altering the extracellular ionic environment of the neuron, the precise ionic mechanism and conductance changes induced in a neuron by a drug or neurotransmitter may be determined.

Patch Clamp Recordings



A final level of analysis to be discussed is one directed at assessing the response of individual ionic channels in the membrane of a neuron. Actually, this technique may be described more as a type of high-resolution extracellular recording. In this method, a glass pipette with a comparatively large tip is drawn, and the tip is fire-polished until it is very smooth. The electrode tip is then placed against the membrane surface of a neuron under visual control. Typically, the neuronal membrane is first cleaned of debris with a jet of fluid to permit a tight seal between the electrode and the membrane. A small suction is then applied to the pipette to tighten its seal with the membrane. Because such an attachment provides a high-resistance junction with the membrane, the minute transmembrane currents that are generated as a result of the opening and closing of individual ionic channels may be monitored. The biophysical characteristics (e.g., open time, inactivation rate) of specific ion channels and how they may be modified by drugs applied via the pipette lumen or to other regions of the neuron being studied can be determined.

Whole-Cell Recordings

A technology widely used in neuropharmacology research is whole-cell recordings. This technique is a modification of the patch clamp technique. The membrane patch underlying the electrode is ruptured, typically by applying a small suction through the pipette, which results in the interior of the electrode becoming continuous with the intracellular fluid. The combination of a tight giga-ohm seal around the electrode–cell membrane junction and the very low resistance of the electrode–intracellular patch has several major advantages: the recordings are very low noise, and the low resistance of the electrodes can minimize errors that may arise during voltage clamp recordings or distort the recorded voltage response to a current input.

When combined with infrared video microscopy techniques, which allow both the large electrode tip and the cell to which it is to be attached to be visualized (Figure 5–6), recordings can be made from specific cell types or from cells labeled with a retrogradely transported fluorescent dye. Although such a preparation has many unique and powerful advantages, this low-resistance junction is also subject to the introduction of artifacts. This is particularly true in cases in which the response to be measured is mediated by diffusible second messengers: the large bore of the attached electrode has been reported to dialyze intracellular constituents from the cell into the electrode. When this process happens, the experimenter often observes a rundown of the response, in which the current gradually decreases with time as a result of loss of the intracellular milieu. To test for this possibility, investigators often rely on a "perforated patch" technique, in which the patch pipette is filled with the ionophore nystatin, gramicidin, or others. When a patch pipette of this type is attached to the cell surface, these channel ionophores are incorporated into the membrane section adjacent to the bore of the electrode. As a result, a low-resistance access to the intracellular space is obtained without the need for rupturing the membrane.

By combining patch clamping with injection of selective dyes, the dynamics of calcium can be imaged in real time within isolated neurons. **(A)** Using infrared differential interference contrast (IR-DIC) microscopy, the image of a patch pipette can be observed attached to a neuron during a whole-cell electrophysiology experiment. Note the relatively large size of the pipette tip *(coming from the left side of the image).* Calibration bar = 2 μm. **(B)** After filling the neuron with a calcium-sensitive dye, bis-Fura 2, the live neuron can be imaged with a fluorescence microscope. The dye takes about 10 minutes to fill the neuron after rupturing the patch membrane. Calibration bar = 10 μm. **(C)** A unique property of the dye bis-Fura 2 is that it changes its fluorescence properties as it binds calcium. This can be observed by the changes in the fluorescence signal in response to a single *(top)* or five *(bottom)* action potentials. The fluorescence traces correspond to two regions, one close to the cell body *(red box* and *red trace)* and one farther out in the apical dendrite *(orange box, orange trace).* In this way, one can observe changes in calcium dynamics and how they correspond to activity states within single neurons.

When penetrating at the level of the soma, the somatic current clamp and voltage clamp recordings are capable of measuring the voltage and conductance changes that occur at the soma or proximal dendrites. As a result, the complex membrane dynamics and synaptic events that occur along the dendritic tree cannot be resolved by somatic penetration in neurons with a complex morphology. One powerful application of patch recording techniques is targeted recordings of dendrites and presynaptic terminals, structures previously not accessible to direct electrophysiological measurement. Recordings at dendritic sites have demonstrated dendritic membrane properties that often are quite distinct from properties determined from somatic recordings. From these findings, it can be inferred that dendrites are not just extensions of the soma but also play an active role in the propagation of postsynaptic potentials from the synapse to the soma.

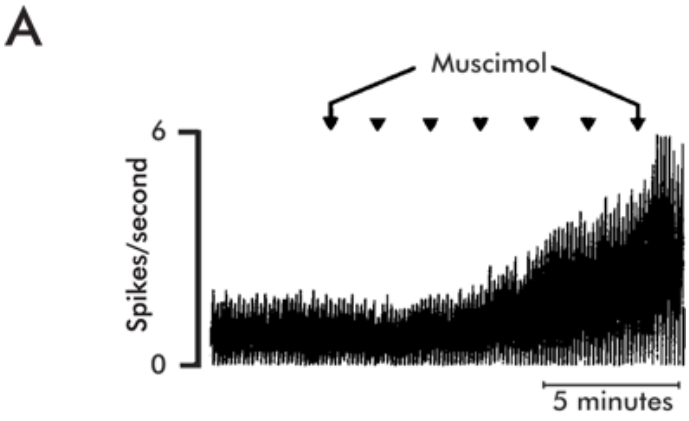
However, many structures, such as finer dendrites and smaller axonals, are still resistant to direct electrophysiological measurement with patch electrodes. Another technique that allows for examination of minute structures is the use of fluorescent dyes. Two basic classes of dyes are commonly used: 1) dyes sensitive to changes in ion concentration, which indirectly reflect the membrane potential, and 2) dyes sensitive to voltage changes, with fluorescence directly responsive to changes of membrane potential. Because these dyes readily diffuse throughout the neuron, real-time imaging of changes in dye fluorescence can be performed in live cells (see Figure 5–6). Although the temporal resolutions and signal-to-noise ratios of imaging technologies do not rival those achievable with direct electrical recordings, imaging allows examination of minute structures and wide spatial regions. Major drawbacks of this technique include the toxicity of some dyes and the phototoxicity induced by light sources used to excite the dyes. More recently, this technique has been applied in vivo, providing new avenues for study of neuronal function.

PREPARATIONS USED IN ELECTROPHYSIOLOGICAL RESEARCH

As with the various types of recordings that can be done, several preparations also can be used in this analysis. No single preparation is "best"; instead, each has specific advantages and shortcomings. A more complete picture of the functioning of a system can be gained by taking advantage of the unique perspective provided by each preparation and designing the experiments accordingly. Except for the first category listed below, all preparations pertain to the mammalian vertebrate.

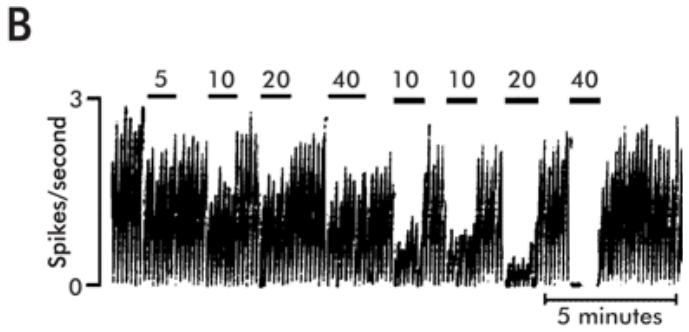
Simpler Nervous Systems—Invertebrates and Lower Vertebrate Preparations

We include a reference to simpler nervous systems for completeness; more comprehensive reviews of the use of nonmammalian model systems can be found elsewhere (Kandel 1978). However, depending on the application, use of these preparations may yield varying degrees of relevance. With respect to the use of phylogenetically lower species as models for psychopharmacological studies in humans, much of the data related to anatomy, cellular physiology, and behavior would be of limited value. The nervous system of these organisms is substantially different from those of vertebrates and humans, even at the single neuronal level. As a result, information derived from these systems is likely to be substantially less applicable to behavioral control in the mammalian class. Nonetheless, several unique advantages are associated with the study of the nervous systems of these organisms: the nervous system is more accessible, the small number of neurons allows for simple and replicable identification of specific neurons, the large neuronal size enables more stable impalement and more complex procedures, and so on. Furthermore, information about the study of some second-messenger systems or receptor transduction mechanisms appears to be more directly transferable to the vertebrate. Thus, it appears that nature is more likely to conserve the most basic functional units of neurotransmitter actions throughout phylogeny, with decreasing levels of homology as the functional units are assembled into more complex systems of neurons and networks.



In Vivo Electrophysiological Recordings

Protocols that use the in vivo preparation focus on the living, intact, anesthetized animal as the subject of the study. Recording the activity of neurons in the intact animal has numerous advantages over studies of isolated tissues. For example, the health of the tissue or neuron under study is more easily maintained and monitored. Furthermore, the neuron can be examined in its normal ionic and cellular microenvironment, with its normal complement of afferent connections intact. In addition, neurons recorded in vivo are more likely to be spontaneously active, facilitating the use of extracellular recordings and investigations into the actions of inhibitory neurotransmitters.



With respect to psychopharmacological research, the in vivo preparation provides the most direct link between neurophysiology and behavior. A drug that elicits a characteristic behavioral response can be administered systemically to examine how the drug affects neurons that are likely to participate in the behavioral response. For similar reasons, this preparation is also the most effective for investigating the mode of action of psychoactive drugs on specific neuronal systems. Although the precise locus of action through which the systemically administered drugs achieve these effects may be difficult to determine directly, whether a given drug ultimately influences the activity of a neuronal system of interest can be determined.

Experimental parameters present difficulties that, although not insurmountable, add complexity to the experimental paradigm. For example, the researcher cannot visually identify the nucleus or the cell to be recorded and must often rely on indirect techniques for cell identification. However, methods are available to enhance the ability to identify cell types. Thus, unlike the in vitro preparations, cells may be identified with respect to the projection sites of their axons by employing antidromic activation—that is, stimulation of the axon terminal region to evoke an action potential that is conducted back down the axon and subsequently recorded at the soma. Furthermore, by using in vivo intracellular recording, the neuron in question may be stained with dye and its location, morphology, and neurotransmitter content identified post hoc by various histochemical and immunocytochemical techniques (e.g., Grace and Bunney 1983; Onn et al. 1994). In addition, although the precise locus of action of systemically administered drugs cannot be determined, the drug effects obtained can be compared with those produced by directly applying the drug to the neuron through microiontophoresis (Figure 5–7) (Bloom 1974). With microiontophoresis, the drug is applied locally to the recording site, affecting the soma and proximal dendrites of the neuron recorded. However, this may be a shortcoming when the afferents to be examined synapse distally on the dendritic tree of the neuron.

There are several means of applying drugs to a neuron to examine their actions. During in vivo recording, drugs may be administered systemically (i.e., intravenously, intraperitoneally, subcutaneously, intraventricularly, intramuscularly) or directly to the neuron by microiontophoresis or pressure ejection. **(A)** Systemic administration of a drug is useful for determining how a drug affects neurons in the intact organism, regardless of whether the action is direct or indirect. In this case, intravenous administration of the γ-aminobutyric acid (GABA) agonist muscimol *(solid arrows)* causes a dose-dependent increase in the firing rate of this dopamine-containing neuron. **(B)** In contrast, direct administration of a drug to a neuron will provide information about the site of action of the drug, at least as it concerns the discharge of the neuron under study. In this case, GABA is administered directly to a dopamine neuron by microiontophoresis. In this technique, several drug-containing pipettes are attached to the recording electrode. The pH of the drug solutions is adjusted to ensure that the drug molecules are in a charged state (e.g., GABA is used at pH = 4.0 to give it a positive charge), and the drug is ejected from the pipette tip by applying very small currents to the drug-containing pipette. Because the total diameter of the microiontophoretic pipette tip is only about 5 μm, the drugs ejected typically affect only the cell being recorded. In this case, GABA is applied to a dopamine neuron by microiontophoresis; the horizontal bars show the time during which the current is applied to the drug-containing pipette, and the amplitude of the current (indicated in nA) is listed above each bar. Note that, unlike the excitatory effects produced by a systemically administered GABA agonist in *(A),* direct application of GABA will inhibit dopamine neurons. This has been shown to be caused by inhibition of a much more GABA-sensitive inhibitory interneuron by the systemically administered drug and illustrates the need to compare systemic drug administration with direct drug administration to ascertain the site of action of the drug of interest.

A technique that overcomes this shortcoming is the use of combined microdialysis and intracellular recording. In this approach, a microdialysis probe is used for *delivering* a drug to the region surrounding the neuron (Figure 5–8). To preserve the tissue surrounding the probe, the probe is lowered at a rate of 3–6 microns per second using a micromanipulator (West et al. 2002b). The microdialysis probe is then allowed to equilibrate for approximately 2–3 hours, and sharp-electrode intracellular recordings are conducted within 500 micrometers of the active surface of the probe. Provided that the probe has been inserted with care, the passive membrane properties, spontaneous spike activity, and spike characteristics of striatal and cortical neurons recorded during perfusion of artificial cerebrospinal fluid are found to be similar to those of neurons recorded in animals without microdialysis. The viability of neurons

recorded proximal to the microdialysis probe is further evidenced by the increase in membrane excitability and spontaneous activity occurring within minutes after introduction of excitatory amino acid agonists (glutamate, *N*-methyl-D-aspartate [NMDA]) or the $GABA_A$ receptor antagonist bicuculline into the perfusate. Conversely, local reverse dialysis of tetrodotoxin eliminates action potentials and the spontaneous plateau depolarizations in prefrontal cortex neurons, indicating that these properties are dependent on synaptic inputs to these neurons. Given these findings, it is clear that this combination method has unique properties in comparison with local application via microiontophoresis. Thus, the site of application will span several hundred micrometers and thereby affect a microcircuit, including the distal dendrites and neighboring neurons of the neuron impaled. Moreover, by applying a neurotransmitter antagonist, one can ascertain the baseline effect of spontaneous neurotransmitter action on a neuron being recorded (West and Grace 2002). This approach has recently been applied to single-unit extracellular recordings (West et al. 2002a) and field potential recordings (Lavin et al. 2005; Goto and Grace 2005a, 2005b).

(A) In this schematic diagram, the relationship between the microdialysis probe and the intracellular recording electrode is depicted. In this case, the neuron recorded is in the striatum. The active surface of the microdialysis probe is shown in gray; this is the area through which the compound is delivered. The probe is implanted very slowly so as not to disrupt the tissue (i.e., 3–6 μm per second) and is perfused with artificial cerebrospinal fluid for 2–4 hours to allow equilibration and settling of the tissue prior to recording. The intracellular recording electrode is then advanced, and a neuron is impaled. After recording baseline activity for 10 minutes, the perfusate is changed to a drug-containing solution to examine the effects on the neuron. **(B)** The histology taken after the recording shows the track of the microdialysis probe; the termination site of the probe tip is indicated by a *dashed arrow.* To confirm that the neuron recorded was near the probe, the neuron is filled with a stain (in this case, biocytin) so as to allow

visualization of the neuron. In this case, the neuron was confirmed to be a medium spiny striatal neuron *(magnified in insert).* ac = anterior commissure. **(C)** Recordings taken from the neuron labeled in B. The *top trace* shows the activity of the neuron while the microdialysis probe is being perfused with artificial cerebrospinal fluid. The neuron demonstrates a healthy resting membrane potential, and spontaneously occurring postsynaptic potentials are evident. The *lower trace* shows the same neuron 15 minutes after switching to a perfusate containing the dopamine D_2 antagonist eticlopride. The neuron shows a strong depolarization of the resting potential (by 12 mV) as well as increased postsynaptic potential activity and spontaneous spike firing. Since the eticlopride is blocking the effects of dopamine that is being released spontaneously from dopamine terminals in this region, we can conclude that basal levels of dopamine D_2 receptor stimulation cause a tonic hyperpolarization of the neuronal membrane and suppress spontaneous excitatory postsynaptic potentials.

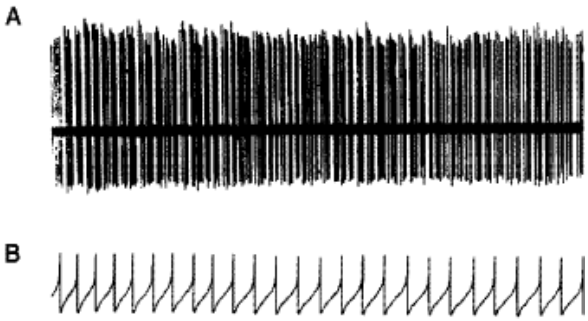
On the other hand, the properties that confer distinct advantages on the in vivo preparation with respect to examining how drugs act in the intact organism also limit the type of data that may be collected. Regarding drug administration, some drugs are not easily applied via microdialysis or do not readily cross the blood–brain barrier, or they may actually produce their direct actions outside of the brain via an effect on peripheral organs. Thus, although dopamine cells can be excited by microiontophoretic administration of cholecystokinin (Skirboll et al. 1981), the excitation produced by systemic administration of this peptide is mediated peripherally and affects the brain via the vagus (Hommer et al. 1985). In addition, the inability to control the microenvironment of the neuron restricts the analysis of the ionic mechanisms underlying cell firing or drug action because the researcher cannot readily control the precise drug concentration or the ionic composition of the fluid surrounding the neuron. There is also difficulty in segregating local actions of drugs versus those imposed on afferent neurons or their local axon terminals. Therefore, whereas the in vivo preparation affords many advantages with respect to examining how behaviorally or therapeutically effective drugs may exert their actions through defined neuronal systems, examination of the site of action or the membrane mechanisms underlying these responses is more readily accessible with in vitro systems.

In Vitro Electrophysiological Recordings From Brain Slices



Recordings of neurons maintained in vitro have led to significant advances in understanding the ionic mechanisms underlying neurotransmitter and drug actions. This preparation consists of slices 300–400 μm thick cut from the brain of an animal soon after decapitation. If this procedure is done carefully and the brain slices are rapidly placed into oxygenated physiological saline, the neurons within the slices will remain alive and healthy, often for 10 hours or more. Because the neurons are recorded in a chamber with oxygenated media superfused over the slice, several advantages may be realized:

1. Both intracellular and extracellular recordings are more stable because blood and breathing pulsations are absent.
2. Visual control over electrode placement is achieved.
3. The ionic composition of the microenvironment may be controlled precisely.
4. Little interference from the activity of long-loop afferents occurs, and the near-absence of spontaneous spike discharge limits the contribution of local circuit neurons to the responses.

Furthermore, in contrast to microiontophoresis, the concentration of drug in the solution can be controlled precisely. This preparation is also the most complex that can be used for patch clamp recordings because debris may be removed and the patch pipette placed on selected neurons under visual control with a high-resolution optics system (Edwards et al. 1989).

Nonetheless, because of the isolated nature of this system, the results obtained may not precisely reflect the physiology of the intact system. For example, dopamine neurons recorded in vivo have been characterized by their burst-firing discharge pattern (Grace and Bunney 1984a), which appears to be important in regulating neurotransmitter release (Gonon 1988). However, dopamine neurons recorded in vitro do not fire in bursting patterns (Grace and Onn 1989) (Figure 5–9). On the other hand, this distinction provides what may be an ideal system for examining the factors that cause in vivo burst firing. Therefore, the most complete model of the functioning of a system or of its response to drug application can be derived by comparing the results obtained in vitro with those in the intact organism.

FIGURE 5–9. Variation (sometimes substantial) in patterns of activity of a neuron type, depending on the preparation in which it is recorded.

(A) Extracellular recordings of a dopamine neuron in an intact anesthetized rat (i.e., in vivo) illustrate the typical irregular firing pattern of the cell, with single spikes occurring intermixed with bursts of action potentials. **(B)** In contrast, intracellular recordings of a dopamine neuron in an isolated brain slice preparation (i.e., in vitro) illustrate the pacemaker pattern that occurs exclusively in identified dopamine neurons in this preparation. For dopamine neurons, a pacemaker firing pattern is rarely observed in vivo, and burst firing has never been observed in the in vitro preparation. However, although the activity recorded in vitro is obviously an abstraction compared with the firing pattern of this neuron in vivo, a comparative study in each preparation does provide the opportunity to examine factors that may underlie the modulation of firing pattern in this neuronal type.

Recordings From Dissociated Neurons and Neuronal Cell Cultures

Recordings from isolated neurons are actually a subset of in vitro recording methods, with many of the same advantages in terms of accessibility and stability. Furthermore, because the neurons can be completely visualized, advanced techniques such as patch clamping are more easily done. A unique advantage of this system can be obtained by coculturing different neuronal populations. For example, defining the effects of a noradrenergic synapse on a hippocampal pyramidal neuron more precisely may be possible by coculturing these cell types and allowing them to make synapses. In this way, the researcher has visual control over impaling neurons that constitute a presynaptic and postsynaptic pairing. On the other hand, the synapses formed are not necessarily limited to those that occur naturally in the intact organism, in terms of both the location of the synapse on the neuron and the classes of neurons that are interconnected. Furthermore, the altered neuronal morphology present in these preparations may modify the response of the neurons to drugs. Nonetheless, when the analysis is limited to well-defined responses, such as second-messenger actions or ion channel measures, this system affords an unparalleled level of accessibility.

RELATIONSHIP BETWEEN BIOCHEMICAL AND ELECTROPHYSIOLOGICAL MEASURES OF NEURONAL ACTIVITY

The methods outlined here are directed at analyzing the activity of individual neurons as a means of assessing their role in pharmacological responses or behavioral actions. This is based on the premise that the discharge of a neuron in some manner reflects its release of a transmitter onto a postsynaptically located target neuron. As such, biochemical measures of neurotransmitter levels would be predicted to correspond to the activity changes occurring during electrophysiological recordings from neurons (Roth 1987). In several cases, such approaches have helped to define the physiological relevance of recorded neuron activity. One case in which this has proven valuable is in the analysis of firing pattern. For example, dopamine neurons, like many other cell types in the central nervous system, are capable of discharging trains of action potentials in two patterns of activity: single spiking and burst firing. However, their range of firing rates is comparatively restricted, with most cells firing only between 2 and 8 Hz. Nonetheless, information on the temporal relationship between spikes and bursts (Grace and Bunney 1984a) has been used in in vivo voltammetry studies to measure dopamine levels. Dopamine cells firing in bursts will release two to three times more neurotransmitter per spike from their terminals than those discharging at similar frequencies but in a steady firing pattern (Gonon 1988). Therefore, in this case, knowledge of the physiological firing pattern provided information to the electrochemist that resulted in the elucidation of the physiological consequence of burst firing in this system.

However, the extrapolation between biochemical and electrophysiological measures may not always be valid. Thus,

recordings from single neurons may not necessarily reflect the activity across the population of neurons of interest. Therefore, a drug that exerts an action via activation of the nonfiring population of neurons may be overlooked if its actions are assessed on single spontaneously discharging neurons (Bunney and Grace 1978; Grace and Bunney 1984b). Furthermore, the response may be confined to a topographically defined subset of neurons mediating a particular response (e.g., a change in the activity of neurons regulating movement of the leg would not be predicted if the response involves a reaching movement of the arm). With respect to biochemical measurements, actions of transmitters at presynaptic terminals could dramatically alter the amount of neurotransmitter they release independent of neuronal discharge (e.g., Grace 1991). On the other hand, electrophysiological measurements enable researchers to examine responses that occur very rapidly. Indeed, a massive but transient activation of spike discharge in a neuronal system may evoke a substantial behavioral response, whereas biochemical measurements of neurotransmitter release performed over a long time course may dilute the impact of the transient event. Therefore, although the results obtained from each measure may not be directly comparable, the electrophysiological measurements are better optimized for detecting transient events.

SUMMARY

In this chapter, we reviewed several electrophysiological techniques and preparations used in the analysis of nervous system function. Each approach is characterized by a set of unique advantages and potential shortcomings inherent in the method. Nonetheless, it should be apparent that no single technique has an overwhelming advantage in psychopharmacological research. Instead, by matching the preparation to the question at hand, and through the judicious comparison of data obtained from intact versus isolated preparations, the various limitations may be systematically overcome to yield a more broadly applicable model of psychopharmacological action.

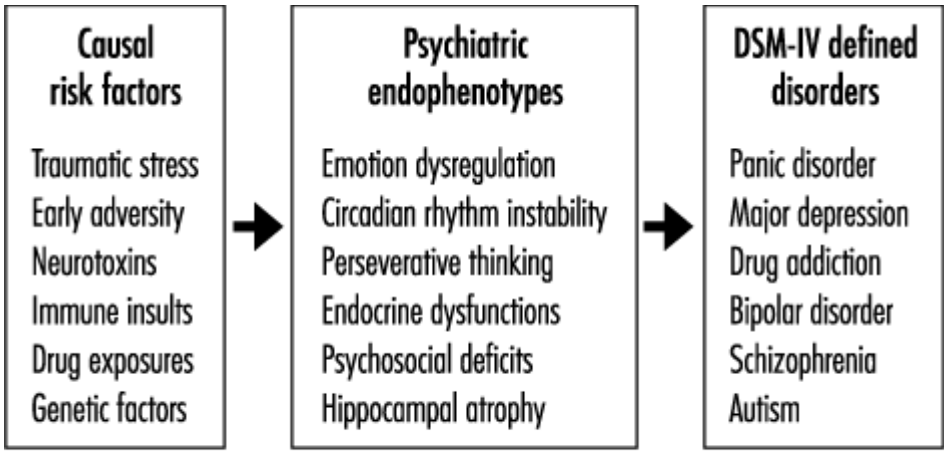
Chapter 6. Animal Models

ANIMAL MODELS: INTRODUCTION

Practical limitations and ethical concerns restrict opportunities for randomized, controlled trials of potentially new drug treatments for human psychiatric disorders. Prospects for discovering the neural mechanisms of action of established therapeutic drugs are also less prevalent in psychiatry than other fields of medicine, because biopsies of diseased brain tissue in humans are seldom performed. Animal models are therefore essential for screening new drugs and for understanding how drug therapies in humans restore the neural basis of mental health. This chapter addresses the validity, utility, and limitations of animal models in psychopharmacological research.

MODEL TYPES AND VALIDITY

Two principal types of animal models are prevalent in psychopharmacology. ***Assay models*** are used to screen drugs with unknown therapeutic potential and need not resemble anything seen in a psychiatric disorder. The validity of assay models is determined by their ability to predict that a drug reliably belongs to a therapeutic class. In rats, for example, passive avoidance deficits induced by olfactory bulbectomies are reversed by antidepressants but not by psychostimulants, neuroleptics, or anticholinergics (Song and Leonard 2005). New drugs with unknown therapeutic potential that reverse bulbectomy-induced deficits in rats are therefore considered to be possible antidepressants. Assay models also satisfy additional criteria, including ease of use, high throughput capacity, reproducibility, and economic concerns.



The second principal type of animal model simulates an aspect of interest in a psychiatric disorder. ***Simulation models*** are used to investigate the biology of psychiatric disorders or the mechanisms of action of psychotherapeutic drugs. In addition to the criterion of ***predictive validity*** described above for assay models, simulation models are often evaluated for two other aspects of validity.

Face validity refers to phenomenological similarities between the animal model and the human psychiatric condition. As originally proposed by McKinney and Bunney (1969), animal models of human mental illness have a high degree of face validity when the following criteria are met: the model is produced by etiological factors known to produce the human disorder, the model resembles the behavioral manifestations and symptoms of the human disorder, the model has an underlying physiology similar to the human disorder, and the model responds to therapeutic treatments known to be effective in human psychiatric patients. How these criteria are evaluated and established has been described in detail elsewhere (McKinney 2001; Weiss and Kilts 1998).

Construct validity refers to the theoretical rationale for linking a psychiatric disorder to an endpoint measured in the animal model. To establish construct validity, a theory for understanding a disorder is mapped or shown to be equivalent to an endpoint in the animal model (Sarter and Bruno 2002). Disease heterogeneity and related concerns that no single animal model can capture the complexities of an entire disorder have shifted attention away from modeling disorders as a whole (McKinney 2001; Insel 2007) to focus on psychiatric endophenotypes (Gould and Gottesman 2006). The endophenotype strategy presupposes that each disorder comprises behavioral, physiological, neuroanatomical, cellular, and molecular components that are more proximal to causal risk factors than are the actual disorders defined in DSM-IV-TR (American Psychiatric Association 2000; Arguello and Gogos 2006).

Psychiatric endophenotypes are conceptualized as mediating the link between genetic or environmental risk factors and the resulting disorder (Figure 6–1). Precise delineation of endophenotypes also serves to highlight the fact that certain features of psychiatric disorders—for example, diminished verbal recall, self-conscious emotions, delusions of control, impaired theory of mind, and suicidal ideation—are likely unique to humans. Many other endophenotypes are, however, amenable to modeling in animal research, as will be described in the following sections of this chapter.

Representative examples and nonexhaustive lists of risk factors, endophenotypes, and disorders are provided to illustrate this theoretical framework for psychiatry neuroscience and psychopharmacological research.

Features that confer a high degree of validity for simulation models are often poorly suited for animal assay models used in drug screening research. An example is the typical delay in response onset for conventional antidepressants. On the other hand, simulation models that achieve all three aspects of validity may be better suited to identify substantively new drugs that differ from those used to establish an assay model. Excessive reliance on assay models may increase the tendency to perpetuate the same side effects as those produced by known medications. The following sections selectively illustrate how animal models have advanced our understanding of the psychopharmacology and biology of depressive disorders.

LEARNED HELPLESSNESS

One of the earliest and most studied models of depression emerged from now classic studies of learned helplessness (Overmier and Seligman 1967; Seligman and Maier 1967) and uncontrollable stress (Weiss 1968). Animals exposed to uncontrollable stress, but not those exposed to controllable stress, exhibit diminished reactivity to rewarding stimulation, altered sleep patterns, social impairments, and deficits in learning appropriate avoidance–escape behavior (Maier 2001; Vollmayr et al. 2004; Weiss and Kilts 1998). Exposure to uncontrollable stress also induces significant changes in noradrenergic (Weiss 1991), serotonergic (Maier and Watkins 2005), and GABAergic (Minor and Hunter 2002) brain systems hypothesized to mediate the behavioral endpoints measured in learned helplessness models. Avoidance–escape deficits in rats are reversed by subchronic treatment with known antidepressants, including tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), selective serotonin reuptake inhibitors (SSRIs), and atypical antidepressants. Stimulants, neuroleptics, sedatives, and anxiolytics do not reverse learned helplessness effects (Weiss and Kilts 1998).

These and related findings demonstrate that learned helplessness models have a high degree of validity in terms of etiology (uncontrollable stress), behavioral symptoms (anhedonia, passivity, disrupted sleep), pathophysiology (sensitization of serotonergic neurons), and response to conventional antidepressants. In rats, however, learned helplessness persists only for several days, whereas depression in humans may last for months. A possible explanation for this discrepancy is that rats do not spontaneously generate perseverative memories or ruminations about their experiences beyond the context in which the experiences occurred. By reminding rats of a stressful experience through repeated exposure to contextual cues, Maier (2001) discovered that learned helplessness manifestations in rats can be prolonged. These findings lend support to the view that stressful perseverative thinking plays a prominent role in the maintenance of human depressive disorders (Brosschot et al. 2006; Nolen-Hoeksema 2000).

CHRONIC STRESS

Chronic stress models in rodents prevent acclimatization by presenting a variety of stressors in an unpredictable sequence over several weeks. Rats exposed to immobilization, immersion in cold water, and other stressors fail to show the typical increase in open-field activity observed in rats not exposed to chronic stress (Katz et al. 1981). A variety of antidepressants restore normal open-field activity in rats exposed to chronic stress, whereas nonantidepressants do not reproduce this effect (Willner 1990). A modified version of the chronic stress model employs milder manipulations, such as exposure to flashing lights, intermittent white noise, and short-term deprivation of food or water. After several weeks of chronic mild stress, rats exhibit decreased consumption of a palatable sucrose solution (Willner 1997). This measure of anhedonia is restored to normal in rats who receive concurrent treatment with an antidepressant during exposure to stress (three different TCAs and two atypical antidepressants were effective in restoring normal consumption behavior). Evidence that antidepressants reverse the anhedonic effects of chronic stress by potentiating dopamine neurotransmission comes from studies in which the therapeutic response to TCAs was reversed by administration of dopamine receptor antagonists (Willner 1997). These findings concur with numerous studies linking dopamine neurotransmission with stress (Pani et al. 2000), reward processing (Martin-Soelch et al. 2001), and the neural mechanisms of action for antidepressants (Willner et al. 2005).

In the original chronic stress model, it was reported that sustained elevations in glucocorticoid levels were restored to normal by antidepressants (Katz and Sibel 1982; Katz et al. 1981). These findings are of interest because patients with major depression often present with increased levels of the glucocorticoid stress hormone cortisol (see Chapter 45, "Neurobiology of Mood Disorders"). In rodents, however, chronically elevated glucocorticoid levels are difficult to maintain (Rivier and Vale 1987; E. A. Young and Akil 1985), and rodent models often rely on manipulations that differ from the stressors that induce or exacerbate depression in humans. An intriguing exception is the visible burrow model, which enables small groups of rats to produce natural stress-engendering social interactions well suited for behavioral, neural, and hormonal investigations of stress pathophysiology (Blanchard et al. 1995).

SOCIAL LOSS

Life events that signify loss or departure from the social network are risk factors for the development of hypercortisolism and depression in humans (Biondi and Picardi 1996; Kendler et al. 2002). A model of social loss–induced hypercortisolism based on species-typical patterns of social organization has been developed in squirrel monkeys (Parker et al. 2003). In their natural environment, squirrel monkeys live in sexually segregated groups. Adult males and females within a group spend most of their time with same-sex companions, and social interactions between the sexes are limited to mating activities (Lyons et al. 1992). When adults are separated from same-sex companions, they respond with increased cortisol levels that frequently persist for several weeks (Lyons and Levine 1994; Lyons

et al. 1999). Hypercortisolism occurs not only when monkeys are separated and temporarily housed alone but also when males and females are housed without same-sex companions in male–female pairs and when males are housed without male companions in multifemale groups (Mendoza et al. 1991).

Hypercortisolism in this animal model is initially driven by hypersecretion of adrenocorticotropic hormone (ACTH). This finding concurs with the widely held view that stress induces hypothalamic release of corticotropin-releasing factor (CRF), which stimulates pituitary secretion of ACTH and thereby triggers secretion of cortisol from the adrenal cortex (see Chapter 7, "Psychoneuroendocrinology"). In socially separated monkeys, however, cortisol levels remain elevated while significant reductions occur in plasma levels of ACTH (Lyons and Levine 1994). Low ACTH levels also occur in the context of hypercortisolism in humans with major depression (Murphy 1991). Despite reductions in ACTH, hypercortisolism is maintained because of enhanced adrenal responsiveness to ACTH in socially separated monkeys (Lyons et al. 1995) and in humans with major depression (Plotsky et al. 1998). The low ACTH levels seen in major depression are also observed in response to administration of CRF (Gold et al. 1986). Metyrapone blockade of cortisol biosynthesis abolishes the attenuated ACTH response to exogenous CRF (von Bardeleben et al. 1988), and metyrapone alone increases baseline ACTH levels in humans with major depression (E. A. Young et al. 1997) and monkeys subjected to social separation (Lyons et al. 1999). These results together suggest that hypercortisolism inhibits the response to excessive CRF at the level of pituitary corticotrophs. Evidence that hypercortisolism and excessive CRF are also involved in behavioral and not just neuroendocrine aspects of depression in humans comes from animal models described in the next section.

PHYSIOLOGICAL MANIPULATIONS

Direct administration of naturally occurring neuropeptides, hormones, and cytokines has been used in animal models to identify physiological factors that induce behavioral symptoms of depression in humans. For example, chronic stress levels of cortisol systemically administered to squirrel monkeys impair prefrontal-dependent cognitive control of impulsive behavior (Lyons et al. 2000). Cortisol administered to healthy humans induces prefrontal-dependent cognitive impairments that resemble those that are caused in humans by prefrontal lesions (Lupien et al. 1999; A. H. Young et al. 1999). Humans with psychotic major depression consistently present with endogenous hypercortisolism (Nelson and Davis 1997), and patients with psychotic major depression are impaired on standardized tests of prefrontal cognitive functions (Schatzberg et al. 2000). Based on these findings, drugs that block cortisol at the receptor level are now being tested as novel treatments for psychotic major depression (DeBattista and Belanoff 2006) and bipolar disorder (A. H. Young 2006).

In various animals, administration of CRF in the brain increases heart rate, arterial blood pressure, limbic brain glucose metabolism, and depressive- and anxiety-like behavior (Heinrichs and Koob 2004; Lowry and Moore 2006; Strome et al. 2002). Conversely, mice genetically engineered to be deficient in the CRF type 1 receptor (CRF-R1) demonstrate diminished depressive- and anxiety-like behavior in response to CRF administration (Muller et al. 2003). These findings from animal models support clinical studies of depression in humans (Nemeroff and Vale 2005) and suggest that drugs that dampen CRF signaling may be therapeutic for patients with depressive disorders. Receptors for CRF, and particularly CRF-R1, are therefore targets of interest in contemporary drug development (Chen 2006).

In rodents and monkeys, peripheral administration of proinflammatory cytokines (i.e., interleukin-1) mimics the effects of stress as a cause of so-called sickness behavior (Hennessy et al. 2001). Sickness behavior in animals is characterized by anhedonia, reduced activity, diminished social and sexual interests, increased sleep, and behaviors reminiscent of depression in humans. Administration of interferon, a potent inducer of proinflammatory mediators, triggers depression in a subset of humans

receiving interferon treatment for cancer or hepatitis C (Asnis and De La Garza 2006). These findings suggest that drugs that block proinflammatory mediators may be novel antidepressants. Recent support for this possibility comes from a guinea pig model of stress-induced sickness behavior (Hennessy et al. 2007).

EARLY LIFE STRESS

Early exposure to parental neglect, child abuse, and severe forms of stress is a risk factor for the development of mood and anxiety disorders. Rhesus macaque monkeys raised without mothers tend to exhibit depression-like behavior (Kraemer 1997), fragmented sleep patterns (Kaemingk and Reite 1987), and excessive consumption of alcohol (Fahlke et al. 2000). Ecologically informed studies of maternal availability have identified similar effects in primate psychosocial development. Bonnet macaque monkeys raised by mothers in stressful variable-demand foraging conditions are impaired on tests of psychosocial and emotional functions (Rosenblum and Andrews 1994). These same monkeys in early adulthood exhibit elevated cerebrospinal fluid levels of monoamines, somatostatin, and CRF (Coplan et al. 2006). Prenatal stress decreases hippocampal volume and inhibits neurogenesis in the dentate gyrus of adolescent rhesus monkey offspring (Coe et al. 2003). Conversely, all known antidepressants increase neurogenesis in the dentate gyrus, as modeled in adult monkeys (Perera et al. 2007), tree shrews (Czeh et al. 2001), and rodents (Drew and Hen 2007).

Hippocampal volumes are smaller in humans with major depression compared with healthy control subjects (Videbech and Ravnkilde 2004), and preliminary evidence in humans suggests that prior exposure to early life stress causes hippocampal volume loss (Vythilingam et al. 2002). To test this hypothesis, we recently examined early life stress and hippocampal volume variation in squirrel monkeys (Lyons et al. 2007). Paternal half-siblings raised apart from one another by different mothers in the absence of fathers were randomized to intermittent postnatal stress or no-stress conditions from 10 to 21 weeks of age. After weaning, at 9 months of age, all monkeys were socially housed in identical conditions. Sexual maturity occurs at 2–3 years of age, and the average maximum squirrel monkey life span is 21 years (Brady 2000). In early adulthood, at 5 years of age, hippocampal volumes were determined in vivo from T1-weighted brain images acquired by magnetic resonance imaging (MRI).

Hippocampal volumes did not differ with respect to prior postnatal stress versus no-stress conditions in squirrel monkeys (Lyons et al. 2001). Rhesus monkeys raised in social isolation do not show hippocampal atrophy despite striking changes in other brain systems and associated behavior (Sanchez et al. 1998). In keeping with studies of humans (Sullivan et al. 2001; van Erp et al. 2004), however, significant heritabilities were discerned by paternal half-sibling analysis of squirrel monkey hippocampal volumes (Lyons et al. 2001). These and related findings suggest that the morphology of specific brain regions is determined in part by genes (Lyons 2002). Moreover, we found that small hippocampal volumes predicted increased stress levels of ACTH after pretreatment with saline or hydrocortisone (Lyons et al. 2007). Small hippocampal volumes may be a risk factor for, and not just an effect of, impaired regulation of the hypothalamic-pituitary-adrenal (HPA) axis response to stress. Similar studies in humans are needed to determine whether small hippocampi are a marker for HPA axis dysregulation in major depression.

GENETIC MANIPULATIONS

Major depression is a heritable disorder that likely involves multiple genes, each with small effects (Wong and Licinio 2001). Targeted gene deletions and gene transfers in animal models are beginning to elucidate the functional significance of potentially relevant genes (Insel 2007). Consider, for example, dysregulation of the HPA axis evinced in depression by an increase in cortisol levels (see Chapter 45, "Neurobiology of Mood Disorders"). Receptors for cortisol are densely expressed in the prefrontal cortex (Webster et al. 2002), where they function as transcription factors that regulate gene expression (Chrousos and Kino 2005). Hundreds of genes in prefrontal cortex appear to be

differentially expressed in humans with a history of major depression based on postmortem analysis of whole-genome microarray data (Choudary et al. 2005; Evans et al. 2004; Iwamoto et al. 2004; Sequeira et al. 2006). Genetic manipulations of receptors for cortisol are not yet feasible in human patients but have recently been studied in various animal models (Boyle et al. 2005; Kaufer et al. 2004; Ridder et al. 2005; Wei et al. 2004). These studies suggest that high-throughput technologies designed to identify candidate genes regulated by receptors for cortisol may yield novel targets for the development of new antidepressants.

Another promising genetic approach involves selective breeding of rodents and subsequent genomewide scans to identify predisposing candidate genes. An intriguing example is the swim-test-susceptible rat, which is bred for extreme passivity in response to uncontrollable stress (Weiss and Kilts 1998). In the swim-test-susceptible rat, eight different antidepressants restore normal swim-test activity after exposure to uncontrollable stress. Four drugs that produce false-positive results in swim tests administered to normal rats (Porsolt et al. 1991) all fail to restore normal swim-test activity in swim-test-susceptible rats. None of the eight tested antidepressants have any effect on a selectively bred line of swim-test-resistant rats, indicating that the detection of antidepressants is best achieved with genetically susceptible rats (Weiss and Kilts 1998). This model is well suited to identify genes involved in a common mechanism of action of diverse antidepressants.

A related strategy combining genetic and developmental approaches to investigate gene–environment interactions is exemplified by studies of BALB/cByJ mice, which typically are more reactive to stress than C57BL/6ByJ mice (Anisman et al. 1998). When stress-susceptible BALB/cByJ mouse pups are raised by stress-resistant C57BL/6ByJ dams, the development of excessive reactivity to stress is diminished in the cross-fostered pups. However, when stress-resistant C57BL/6ByJ pups are raised by stress-susceptible BALB/cByJ dams, the development of subsequent stress reactivity is not affected in the cross-fostered pups. This model demonstrates that genetic factors affect mother–infant interactive styles, which in turn influence the subsequent development of stress susceptibility in mice.

A complementary approach involves targeted disruptions of gene expression in specific brain regions only during critical periods of postnatal brain development. An example is provided by mice engineered to lack the serotonin$_{1A}$ receptor (5-HT1AR) protein. These mice exhibit increased anxiety-like behavior on a variety of tests. Selective expression of 5-HT1AR in the hippocampus and cortex, but not the raphe nuclei, restores to normal the behavior of 5-HT1AR knockout mice (Gross et al. 2002). Additional evidence suggests that tissue-specific 5-HT1AR expression during postnatal development, but not in adulthood, is necessary to achieve the behavioral rescue effect. This model indicates that developmental changes in 5-HT1AR gene expression within specific brain regions are involved in the emergence of anxiety-like behavior in adulthood.

UTILITY AND LIMITATIONS

Most animal models used to study aspects of depression in humans have utilized males, but the prevalence of depression in humans is nearly two times higher in women than in men (Shively et al. 2005). Another limitation of animal models is the tendency to focus on single factors as the cause of depression in humans (Willner 1990). In certain cases, one causal factor may be identified, but more often than not, depression evolves from a nexus of causal risk factors that accumulate over the life span (Kendler et al. 2002). Attempts to model aspects of depression in animals based on one causal factor may be impractical if no single factor is sufficiently potent to trigger the development of depression in humans.

Prefrontal cortical enlargement in humans and associated cognitive complexities raise additional concerns for animal models of psychiatric disorders (Keverne 2004). The difficulty stems from problems in identifying homologous brain regions in humans and animals (Porrino and Lyons 2000;

Preuss 1995; Sasaki et al. 2004), especially for the rodents now widely used in neuroscience research. Transgenic mouse models likewise require homologous genes, and the resulting mouse phenotypes are not necessarily isomorphic with the human condition, because genes expressed on different backgrounds can produce different phenotypes (Yoshiki and Moriwaki 2006).

Despite these concerns, many important aspects of human psychiatric disorders are amenable to modeling in animal research. Because the life span of most animals is shorter than that of humans, longitudinal studies of development are facilitated by animal models. Randomized, controlled experiments can be conducted in animals without the common confounds that characterize clinical studies, such as comorbidity, polydrug abuse, and medication effects. Animal models also provide brain tissue of the highest possible quality for cellular and molecular research. Discoveries first made in clinical settings and subsequently tested in animals form the foundation of psychiatric neuroscience and will continue to play a key role in psychopharmacological research.

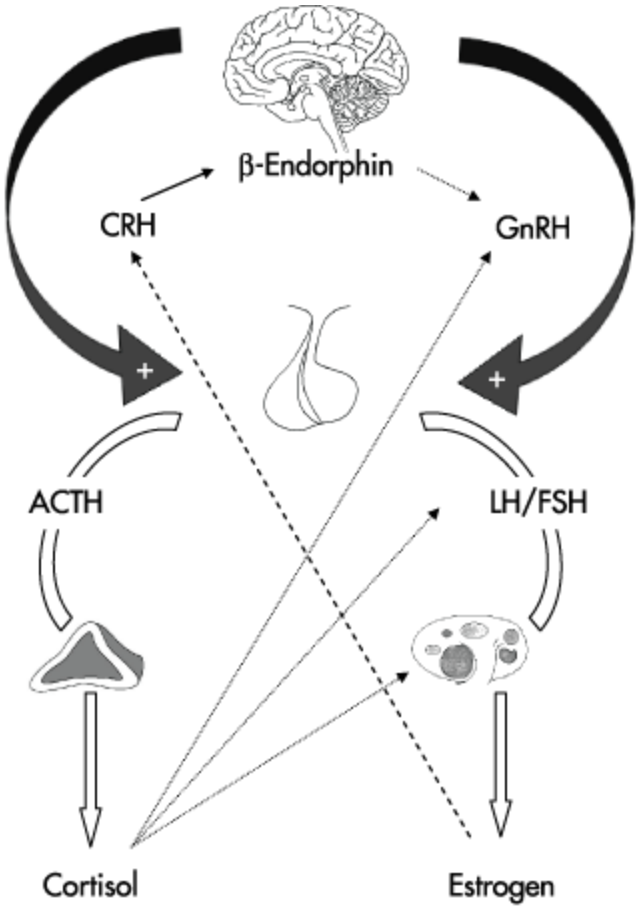
Chapter 7. Psychoneuroendocrinology

PSYCHONEUROENDOCRINOLOGY: INTRODUCTION



An association between hormones and psychiatric disorders has been long recognized, but it is only in the past few decades that we have reached an understanding of the mechanisms underlying this association. A full account of the myriad ways in which the various endocrine systems influence neurobehavioral function would be beyond the scope of a single chapter. We will therefore focus on examples of promising research directions in this area: namely, how the stress and reproductive hormone axes contribute to the pathoetiology of psychiatric conditions, in particular mood and anxiety disorders.

Major depression is considered to be a maladaptive, exaggerated response to stress, and although it is accompanied by abnormalities in multiple endocrine systems, it is the hypothalamic-pituitary-adrenal (HPA) axis that is the main component of the physiological stress response that plays the key role. Stressful life events, particularly those related to loss, have a strong causal relationship with depressive episodes. However, not all people who experience such events develop depression, and an individual's vulnerability to depression depends on the interaction of genetic, developmental, and environmental factors. In addition to the role of the HPA axis in depression, there is growing evidence of HPA axis abnormalities in anxiety disorders and posttraumatic stress disorder (PTSD).

HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The HPA axis transforms stressful stimuli into hormonal messages that enable the organism to adapt to environmental change and to maintain the body's homeostasis. Corticotropin-releasing hormone (CRH) is synthesized in the hypothalamus and is stimulated by stressors, which can be either "physical" (e.g., exercise, starvation) or "psychological" (e.g., perceived danger, stressful life events). The HPA axis is closely linked to the autonomic nervous system, and brain stem catecholamine systems can also "activate" CRH release (Herman et al. 1990; Plotsky 1987; Plotsky et al. 1989). CRH stimulates secretion of pituitary adrenocorticotropic hormone (ACTH), resulting in the secretion of glucocorticoids by the adrenal cortex in a feedforward cascade. Cortisol is the main glucocorticoid, and its secretion is tightly controlled by negative feedback effects of glucocorticoids at both pituitary and brain sites. These comprise very rapid real-time inhibition of the stress response that prevents oversecretion of glucocorticoids (Keller-Wood and Dallman 1984) and results in a slower effect on messenger ribonucleic acid (mRNA) and subsequent protein stores for both CRH and the ACTH precursor, pro-opiomelanocortin (Roberts et al. 1979) (Figure 7–1).

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone.

Stressful stimuli activate all levels of the HPA axis, causing increases in CRH, ACTH, and cortisol secretion. However, these increases are superimposed on an intrinsic circadian pattern of HPA activity driven by the suprachiasmatic nucleus (SCN) (Krieger 1979). HPA axis hormone secretion is pulsatile in nature, with the trough of integrated secretion occurring in the evening and early night and the peak of secretion occurring just before awakening; active secretion continues throughout the morning and early afternoon. This rhythm persists even in the absence of corticosteroid feedback (e.g., adrenalectomy [Jacobson et al. 1989]), and there is evidence that there are intrinsic neural elements responsible for both initiation and inhibition of the CRH/ACTH/cortisol circadian rhythm and that glucocorticoids merely act to dampen the overall amount of secretion (Kwak et al. 1993).

HPA Axis in Depression and Anxiety Disorders

Depression

Overactivity of the HPA axis as manifested by an increase in cortisol secretion is now a well-established phenomenon in depression (Carroll et al. 1976; Sachar et al. 1973). The first studies (Sachar et al. 1973) showed that up to 50% of depressed patients have higher mean plasma cortisol concentrations and an increased number and duration of cortisol secretory episodes, suggesting increased cortisol secretory activity. Numerous studies have subsequently validated these findings (Carroll et al. 1976; Halbreich et al. 1985; Krishnan et al. 1990a; Pfohl et al. 1985; Rubin et al. 1987). As many as two-thirds of endogenously depressed patients fail to suppress cortisol, or show an early

escape of cortisol, following overnight administration of 1 mg of dexamethasone (using a cortisol cutoff of 5 μg/dL to define "escape") (Carroll et al. 1981). While nonsuppression of cortisol in response to dexamethasone is strongly associated with endogenous depression, this finding is less robust in outpatients with depression. Although both hypercortisolemia and feedback abnormalities in response to dexamethasone are present in depressed patients, they do not necessarily occur in the same individuals (Carroll et al. 1981; Halbreich et al. 1985). Other abnormalities, such as reduced glucocorticoid fast feedback (Young et al. 1991) and a blunted ACTH response to exogenous CRH, have also been reported in depressed patients (Gold et al. 1986; Holsboer et al. 1984; Young et al. 1990).

The blunted response to CRH appears to be dependent on increased baseline cortisol, since blockade of cortisol production with metyrapone normalizes the ACTH response (Von Bardeleben et al. 1988; Young et al. 1995). It was expected that the increased cortisol would be accompanied by an increased level of ACTH in plasma, but this has been difficult to validate, although several studies (Linkowski et al. 1985; Pfohl et al. 1985; Young et al. 2001) have demonstrated small differences in mean 24-hour plasma ACTH levels between healthy control subjects and depressed subjects. The demonstration of enhanced sensitivity to ACTH 1–24 in depressed patients suggests that increased ACTH secretion is not necessarily the cause of increased cortisol secretion (Amsterdam et al. 1983). However, other studies using very low "threshold" doses of ACTH 1–24 have not been able to demonstrate increased sensitivity to ACTH in depressed patients (Krishnan et al. 1990b), which suggests that increased cortisol secretion is secondary to increased ACTH secretion. Our 24-hour studies of ACTH and cortisol secretion demonstrated that subjects with increased mean cortisol also demonstrated increased mean ACTH, supporting a central origin of the HPA axis overactivity (Young et al. 2001). Further studies with metyrapone in major depression also support the presence of increased central nervous system (CNS) drive, at least in the evening (Young et al. 1994, 1997). It appears likely that there is increased CRH/ACTH secretion, which is then probably amplified by the adrenal, leading to increased cortisol secretion.

These changes in cortisol secretion are commonly considered to be "state" changes that resolve when the depression resolves. However, almost all studies examining the HPA axis in major depression in euthymic subjects have examined patients on tricyclic antidepressants, which exert direct effects on the HPA axis. Three of our recent studies in epidemiological samples and a recent British study (Bhagwagar et al. 2003) found that salivary cortisol is increased in subjects with *lifetime* major depression, most of whom had no current mood symptoms (Bhagwagar et al. 2003; Young et al. 2000a). The overall picture suggests that depression generally shows both an increase in activity of circadian activational elements of the system and reduced feedback inhibition.

Anxiety Disorders

The HPA axis has also been studied in patients with anxiety disorders, particularly panic disorder, with and without comorbid major depression. Both the cortisol response to dexamethasone and the response to CRH have been examined in pure panic disorder without comorbid depression. The earliest study with dexamethasone demonstrated a 15% nonsuppression rate in panic disorder (Curtis et al. 1982). A number of other studies have since been conducted, and the overall incidence of cortisol nonsuppression is 17% in panic disorder (13 studies), while the incidence for major depression is 50% (Heninger 1990). Grunhaus et al. (1987) compared patients with major depression to those with major depression with panic disorder and found a similar rate of cortisol nonsuppression following dexamethasone administration (approximately 50%) in the two populations, suggesting that the presence of comorbid panic disorder had little impact beyond that of depression on dexamethasone nonsuppression. In CRH challenge tests, panic disorder patients have demonstrated a decreased integrated ACTH response relative to control subjects in some studies (Holsboer et al. 1987; Roy-Byrne et al. 1986) but a normal response in others (Brambilla et al. 1992). Similar to findings in

depression, "baseline" plasma cortisol was increased in panic patients who showed blunted CRH responses. A study of CRH challenge in panic disorder patients (Curtis et al. 1997) demonstrated a normal response to CRH challenge.

Studies of the HPA axis in social phobia have not found evidence of baseline hyperactivity by urinary free cortisol (Uhde et al. 1994), although few challenges other than a social speaking task have been used. Public speaking challenges in anxiety disorders do not support an exaggerated ACTH or cortisol response to this stressor (Gerra et al. 2000; Levin et al. 1993; Martel et al. 1999). A few studies in children with anxiety disorders have also examined the HPA axis. Children with anxiety disorders coming in for a CO_2 challenge demonstrated elevated "basal" cortisol in those who panicked in response to CO_2, suggesting that increased reactivity to a threatening situation (i.e., anticipation of a procedure that would cause discomfort) was linked to activation of the HPA axis (Coplan et al. 2002). This interpretation is further supported by an extremely large study of basal 24-hour cortisol in normal children and children with either anxiety disorders or major depression, which found lower nighttime cortisol and a sluggish morning rise in cortisol in children with an anxiety disorder. This suggests that anxiety disorders lead to stress hyperreactivity (in the case of anxious children, in the context of a threatening experimental procedure of CO_2) with compensatory decreased basal cortisol secretion (24-hour study) (Feder et al. 2004).

Overall, the studies to date do not suggest HPA axis hyperactivity in anxiety disorders to the same extent as shown in depression (Abelson and Curtis 1996). Feedback elements are generally normal, and the abnormalities that do exist may reflect "extrinsic" factors that contribute to heightened reactivity within activational elements of the system. The question of whether stress-activated HPA axis elements are abnormal in comorbid major depression and anxiety has not yet been well studied.

Posttraumatic Stress Disorder

Given the stress-related etiology of PTSD, it was expected that PTSD patients would show HPA axis abnormalities similar to those seen in depressed patients or chronically stressed animals, but this has not always been the case. An initial study (Mason et al. 1986) found that urinary free cortisol (UFC) excretion was *lower* in PTSD than in major depression. However, another study (Pitman and Orr 1990) found *increased* UFC excretion in outpatient PTSD veterans compared with combat-exposed control subjects without PTSD. Since then, there have been various findings, but the most comprehensive studies of PTSD, those by Yehuda and colleagues (for a review, see Yehuda 2002), continue to show low cortisol and enhanced cortisol suppression in response to dexamethasone in combat veterans with PTSD. Interestingly, the presence of comorbid major depression does not change the neuroendocrine picture. The main criticism of this body of work is that the sample comprised only male combat veterans and therefore is not representative, given that in the community, it is women who are most likely to experience PTSD (Breslau et al. 1991, 1995; Kessler et al. 1995). Furthermore, significant confounds with current and past alcohol and substance abuse occur in the veteran population.

Several studies have sought to address this problem, with the majority examining women with a history of childhood sexual abuse. While some studies have demonstrated increased UFC in women with PTSD or a history of abuse compared with control subjects (Lemieux and Coe 1995), others have demonstrated similar plasma cortisol (Rasmusson et al. 2001), and still others have found lower cortisol and enhanced cortisol suppression in response to dexamethasone (Stein et al. 1997). Yehuda (2002) examined Holocaust survivors, who were also predominantly exposed early in life, and observed lower UFC and enhanced cortisol suppression following dexamethasone administration in this population. The issue of comorbid depression in the PTSD population has not been well addressed, with most studies including comorbid individuals and few analyzing the data by the presence or absence of comorbid depression. The exception is the studies of Heim et al. (2001), which focused on childhood abuse and major depression and examined multiple HPA axis challenges in the same subjects. These studies found an effect of early abuse (with comorbid PTSD in 11 of 13 subjects) and

major depression on stress reactivity, with both increased ACTH and cortisol response to the stressor compared with either healthy control subjects or depressed patients without childhood abuse. In this same cohort, there was a blunted response to CRH challenge in patients who had major depression with or without childhood abuse, but an increased response to CRH in those with early abuse but without major depression. The abused subjects also showed a blunted cortisol response to ACTH 1–24. Thus, childhood abuse produced an increased pituitary response with adaptive adrenal compensation, a change compatible with low or normal basal cortisol. Furthermore, lower cortisol and enhanced feedback to low-dose dexamethasone were found in the same subjects (Newport et al. 2004) regardless of the presence or absence of PTSD as the primary diagnosis, thus indicating enhanced feedback.

Epidemiologically based samples in adults have focused on natural disasters and have generally examined exposure with high and low PTSD symptoms (Anisman et al. 2001; Davidson and Baum 1986; Fukuda et al. 2000) but without diagnostic information. However, one study (Maes et al. 1998) that examined PTSD subjects recruited from community disasters demonstrated increased UFC in PTSD. In general, community-based studies suggest that exposure to disaster increases plasma (Fukuda et al. 2000) and saliva cortisol (Anisman et al. 2001) and UFC (Davidson and Baum 1986). Studies examining motor vehicle accident survivors (Hawk et al. 2000) found no difference in cortisol between those with and without PTSD 6 months later. Studies of male and female adults with exposure to mixed traumas have found either no effect of PTSD on basal cortisol (Kellner et al. 2002, 2003) or elevated basal cortisol (Atmaca et al. 2002; Lindley et al. 2004). Our analysis of recent trauma exposure in two community samples (Young and Breslau 2004a, 2004b; Young et al. 2004) found increased cortisol in those with past-year exposure to trauma, but no effect of greater than 1 year past trauma exposure and no effect of childhood abuse on basal saliva cortisol or UFC. To add further complexity, the majority of studies of trauma and PTSD included subjects with comorbid depression, and in most studies, the majority of subjects had both PTSD and major depression. The PTSD studies generally report comorbid depression in their subjects; however, studies of depression often fail to measure and report trauma histories. As a result, documented depression confounds much of the PTSD HPA axis literature, and undocumented trauma and abuse may confound some of the depression HPA axis literature.

In addition to the issue of exposure to trauma, the persistence of the neuroendocrine changes following recovery from PTSD is unclear. In an early study, Yehuda et al. (1995) reported that Holocaust survivors with past but not current PTSD demonstrated normal UFC, while later studies of offspring of Holocaust survivors (Yehuda et al. 2002) suggested that changes in cortisol may persist beyond the duration of the symptoms and thus may represent a marker of underlying vulnerability to PTSD. The large analysis by Boscarino (1996) of cortisol data from several thousand combat veterans showed a very small effect of PTSD on basal cortisol, but a very clear effect of combat exposure, with increasing levels of severity of combat exposure associated with increasingly lower cortisol.

Our recent studies of cortisol in PTSD from two epidemiological samples (Young and Breslau 2004a, 2004b; Young et al. 2004) demonstrated normal UFC and saliva cortisol in community-based individuals with "pure" and comorbid PTSD. The studies also demonstrated a clear effect of lifetime comorbid major depression on cortisol, showing increased HPA axis activation in the late afternoon/evening in patients with both major depression and PTSD. Furthermore, the elevated HPA drive demonstrated by increased evening cortisol levels was greater in the comorbid group than the elevation already documented in pure major depression.

Studies examining the response to low-dose dexamethasone in PTSD veterans found enhanced feedback to dexamethasone in veterans who met criteria for PTSD, regardless of the presence of comorbid major depression (Yehuda et al. 2002). Similar enhanced cortisol suppression in response to dexamethasone administration has been found in Holocaust survivors with PTSD and their offspring.

In the studies of Yehuda (2002) as well as the report by Stein et al. (1997), the enhanced suppression was also paired with low baseline cortisol, although other studies did not replicate this finding (Kellner et al. 2004a, 2004b).

In a CRH challenge study in combat-related PTSD, there was a normal to increased plasma cortisol at the time of challenge (Smith et al. 1989) and a decreased ACTH response in subjects with high baseline cortisol. Another study of women with PTSD and a history of childhood abuse (Rasmusson et al. 2001) showed enhanced cortisol response to CRH and to exogenous ACTH infusion, as well as a trend toward higher 24-hour UFC. Interestingly, all the women with PTSD had either past or current major depression, so comorbidity was the rule. In the study by Heim et al. (2001) examining response to CRH in women with major depression with and without childhood abuse, 14 of 15 major depressive disorder patients with childhood abuse also met criteria for PTSD. This group with comorbid major depression and PTSD demonstrated a blunted ACTH response to CRH challenge similar to that observed in major depression without PTSD. The abused groups also demonstrated lower baseline and stimulated cortisol both in response to CRH challenge and following ACTH infusion. These same groups of women showed a significantly *greater* HPA response to the Trier Stress Test, despite *smaller* responses to CRH challenge (Heim et al. 2000).

Several additional studies have evaluated response to stressors. Our early study (Liberzon et al. 1999) using combat noise versus white noise in male veterans with PTSD showed elevated basal and postprovocation cortisol compared with combat controls but no real evidence of a difference between the combat and white-noise days. A study by Bremner et al. (2003) of PTSD subjects of both sexes used a stressful cognitive challenge and found elevated basal saliva cortisol and continued higher cortisol for 60 minutes postchallenge. Eventually the saliva cortisol of the PTSD group returned to the same level as that of controls, raising the issue of whether the "basal" samples were truly basal or were influenced by the anticipatory challenge. Similar data were found in a study (Elzinga et al. 2003), using trauma scripts, in women with childhood abuse and PTSD compared with abused women with no PTSD. In that study, salivary cortisol was again significantly elevated at baseline, increased in response to the challenge (whereas controls showed no response), and then greatly decreased following the stressor, compatible with "basal" levels already reflecting exaggerated stress sensitivity in this group. Using a 1-minute cold pressor test, a recent study (Santa Ana et al. 2006) compared the ACTH and cortisol response in PTSD subjects with either childhood trauma or adult trauma with that of control subjects and found lower basal cortisol in the childhood abuse group. However, their data do not support an actual change in ACTH or cortisol in response to the stressor in any group, so it is difficult to interpret their findings as reflecting differences in stress response. In addition, sampling was very infrequent and therefore inadequate to characterize the time course to a very *brief* stressor. Overall, the existing stress data suggest an exaggerated stress response in PTSD.

Furthermore, the challenge studies certainly suggest that the picture is complicated in PTSD with comorbid depression; the findings of some studies look like depression while others look quite different—for example, showing a smaller response to ACTH infusion whereas patients with major depression show an augmented response. Age of trauma exposure may be one reason for contradictory data. Finally, one study by Yehuda (2002) of combat veterans with PTSD demonstrated greater rebound ACTH secretion compared with controls following administration of metyrapone in the morning, indicating that increased CRH drive is present in the morning but is normally restrained by cortisol feedback. The other two studies examining metyrapone challenge in PTSD found a normal ACTH response to afternoon or overnight metyrapone as well as a normal response to cortisol infusion in PTSD subjects and panic disorder subjects (Kanter et al. 2001; Kellner et al. 2004a, 2004b). In summary, these data suggest that there may be no simple relationship between diagnostic categories and specific HPA axis abnormalities. Timing of trauma or of onset of depression or anxiety disorders may differentially affect the HPA axis profile, although definitive studies have not been done.

DEPRESSION AND REPRODUCTIVE HORMONE CHANGES

In women with a previous episode of depression, times of rapidly changing gonadal steroid concentrations, such as those occurring premenstrually or postpartum, mark particularly vulnerable times for the occurrence of depressive symptoms. Several studies have shown that in women, a history of depression increases the risk of both postpartum "blues" and postpartum major depression (O'Hara 1986; O'Hara et al. 1991; Reich and Winokur 1970) and that hormonal changes occurring premenstrually may affect mood (Halbreich et al. 1984, 1986). When they were euthymic, 62% of women with a history of major depressive episodes reported the occurrence of premenstrual mood changes and biological symptoms typical of major depressive disorder. Other studies found a relationship between the rise in estrogen and testosterone levels and the rising incidence of depression in girls during adolescence (Angold et al. 1999). More recently in two epidemiological cohorts (Cohen et al. 2006; Freeman et al. 2006), there was an increased incidence of depressive symptoms and major depression during the menopausal transition. Both high and low estrogen were associated with depression (Freeman et al. 2004, 2006), and the variability in estrogen levels may drive depression—that is, those women who show rapid changes from high to low estrogen and vice versa are those who develop depressive symptoms during the perimenopause transition. This suggests that examining the reproductive axis in depression may be a fruitful area of psychoneuroendocrine research.

HYPOTHALAMIC-PITUITARY-GONADAL AXIS

The secretion of the principal gonadal steroids, estrogen and progesterone, is governed by cyclic changes in ovarian follicular and corpus luteum development over the course of the menstrual cycle. Critical to the proper functioning and timing of the monthly hormonal cycle is the pulsatile secretion of gonadotropin-releasing hormone (GnRH). GnRH secretion from the hypothalamus drives the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotropes (Midgley and Jaffe 1971). During the early follicular phase, FSH plays the major role in maturing the follicle (diZerega and Hodgen 1981), and the developing follicle secretes increasing amounts of estradiol as it matures. Maturation-induced increases in estradiol exert a negative feedback on FSH secretion and both negative and delayed positive feedback effects on LH secretion (Karsch et al. 1983). The change in estradiol feedback from negative to positive late in the follicular phase is complemented by rising progesterone and results in the midcycle surge in LH necessary for ovulation. Following ovulation, progesterone levels continue to rise as a result of active secretion from the corpus luteum. LH secretion is necessary for the maintenance of the corpus luteum and subsequent estrogen and progesterone secretion and also facilitates estradiol production by the follicle and controls the secretion of hormones by the corpus luteum but is inhibited by progesterone (Chabbert et al. 1998). In the absence of fertilization, regression of the corpus luteum occurs, with the subsequent fall in estrogen and progesterone leading to the onset of menses.

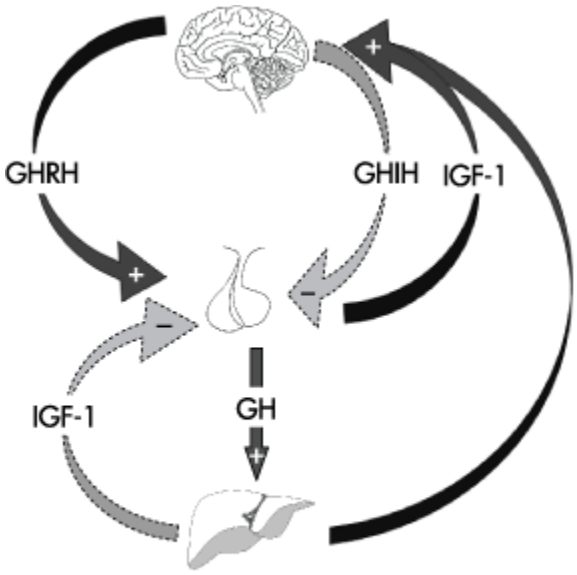
The pulsatile secretion of GnRH is driven by a pulse generator in the arcuate nucleus of the hypothalamus (Knobil 1990). This pulsatile pattern of GnRH secretion is critical for the control of serum LH, FSH, and ovulation. Indeed, continuous administration of the GnRH agonist leuprolide in a nonpulsatile pattern suppresses ovulation as effectively as does inadequate secretion of GnRH. Studies in primates with arcuate lesions have demonstrated that administration of GnRH pulses in frequencies that are too fast or too slow results in low serum concentrations of LH (Belchetz et al. 1978).

LH secretory pulses in the peripheral circulation are used as the marker of GnRH secretory pulses. In humans, the follicular phase of the menstrual cycle is characterized by reasonably constant amplitude LH pulses every 1–2 hours (Reame et al. 1984). During the luteal phase, pulse amplitude becomes much more variable and pulse frequency decreases. The slowing of the LH pulses during the luteal phase is due to the actions of progesterone on the GnRH pulse generator (Goodman and Karsch 1980;

Soules et al. 1984; Steele and Judd 1986). Gonadal steroids exert negative feedback effects on the amplitude and frequency of GnRH pulses and through this mechanism (in addition to direct actions on the pituitary) inhibit the secretion of LH and FSH. Likewise, central opioids, particularly β-endorphin, exert a tonic inhibition on GnRH secretion (Ferin and Vande 1984). Circadian changes in LH secretion are not as prominent as those of the HPA axis (Jaffe et al. 1990). During puberty and following recovery from anorexia- or exercise-induced amenorrhea, nighttime secretion of LH becomes particularly prominent. Furthermore, nighttime slowing of LH pulses during the early follicular phase also occurs in normal women (Soules et al. 1985).

Effect of HPA Axis on the Reproductive Axis

Stress has long been known to inhibit the reproductive axis, and the work of Christian (1971) demonstrating infertility secondary to high population density is often cited as a seminal report. Shortly after the isolation and sequencing of CRH, it was demonstrated in rats that CRH inhibited LH secretion (Rivier and Vale 1984) and GnRH secretion (Petraglia et al. 1987), and further primate studies showed inhibition of LH secretion by injection of CRH (Olster and Ferin 1987).



While early studies used peripheral administration of high doses of CRH, subsequent studies demonstrated that intracerebrovascular administration of CRH demonstrated much greater potency and confirmed a central site of action of the inhibition, pointing to direct inhibition of GnRH by CRH (Gambacciani et al. 1986; Nikolarakis et al. 1986a, 1986b; Olster and Ferin 1987; Petraglia et al. 1987). However, the peripheral administration of CRH also demonstrated an opioid-mediated inhibition by CRH that could be abolished by dexamethasone pretreatment, suggesting a role for pituitary-derived opioids, most probably β-endorphin from anterior pituitary corticotropes. Anatomical studies demonstrate that CRH neurons synapse with GnRH neurons (MacLusky et al. 1988); in vitro studies demonstrate that CRH can function as a secretagogue for β-endorphin secretion from the arcuate β-endorphin system (Nikolarakis et al. 1986a). Studies in primates by the Knobil laboratory (Williams et al. 1990) recording multiunit activity from the arcuate nucleus (i.e., the GnRH pulse generator) demonstrated that CRH administration induced inhibition of the rhythmic firing of the arcuate nucleus accompanying LH secretory pulses, as well as abolishing LH pulses. Studies with a CRH antagonist, α-helical CRH_{9-41}, demonstrated the antagonist's ability to reverse stress-induced LH suppression in rats, confirming a central CRH-based mechanism by which stress inhibits LH secretion (Rivier et al. 1986). While the primate and rat studies have clearly pointed to CRH as the primary mechanism by which stress inhibits GnRH release, this is not true in all species (e.g., central CRH has no effect on GnRH or LH secretion in sheep [Tilbrook et al. 1999]), and some stressors act through cortisol (Debus et al. 2002). The demonstration of a central CRH effect on GnRH release does not preclude an effect of cortisol in both rats and primates, including humans.

So is there evidence that cortisol may also be involved in the inhibition of reproductive function? Several studies have demonstrated that ACTH administration reduces the increase in serum LH concentrations following ovariectomy or orchidectomy in rats (Mann et al. 1982; Schwartz and Justo 1977). This effect is dependent on the presence of the adrenal but could also involve adrenal production of gonadal steroids, which is regulated by ACTH (Putnam et al. 1991). Glucocorticoids also exert inhibitory effects on GnRH secretion or LH responsiveness to GnRH, including direct effects of cortisol on the gonadotrope (Suter and Schwartz 1985). Radovick et al. (1990) demonstrated a glucocorticoid-responsive element (GRE) on the *GnRH* gene, providing the potential for glucocorticoids to modulate *GnRH* gene expression. Diminished LH response to GnRH following long-term prednisolone treatment has been found in women (Sakakura et al. 1975). Patients with Cushing's disease, in which cortisol is increased but central CRH is likely to be low because of excessive glucocorticoid feedback on paraventricular nucleus of the hypothalamus CRH, show inhibition of LH secretion. Recent studies in ewes have found that 1) LH secretory amplitude is clearly inhibited by stress; 2) the effects of stress or endotoxin are reversed by metyrapone inhibition of cortisol

synthesis; and 3) infusion of stress levels of cortisol can produce inhibition of LH pulse amplitude but not frequency, which is blocked by RU486, a glucocorticoid receptor antagonist (Breen et al. 2004; Debus et al. 2002). Finally, a recent study of exercise-induced reproductive abnormalities in adolescent girls concluded that "in active adolescents, increased cortisol concentration may. . . precede gonadotropin changes seen with higher levels of fitness" (Kasa-Vubu et al. 2004, p. 1). These data suggest that cortisol, in addition to central CRH, may also play a role in LH disruption.

Other studies in humans have linked hypothalamic-pituitary-gonadal (HPG) axis abnormalities to HPA axis activation. These include exercise-induced amenorrhea, anorexia nervosa, and hypothalamic amenorrhea. In all three syndromes, hypercortisolemia has been observed, indicating overactivity of the HPA axis (Berga et al. 1989; Casanueva et al. 1987; Hohtari et al. 1988; Loucks et al. 1989; Suh et al. 1988; Villanueva et al. 1986). In all three syndromes, CRH has been used as a challenge to evaluate pituitary and adrenal function. The response to exogenous CRH challenge demonstrates diminished ACTH or cortisol responses, suggesting that high baseline cortisol exerts negative-feedback effects on the hormonal responses to CRH (Berger et al. 1983; Biller et al. 1990; Gold et al. 1986; Hohtari et al. 1991). In anorexia nervosa, the hormonal abnormalities in both HPA and HPG axes are secondary to weight loss. Weight restriction and low body weight are also observed in exercise-induced amenorrhea, and low body weight has been reported in hypothalamic amenorrhea. Even relatively mild degrees of weight loss in normal-weight or obese subjects can lead to disturbances in both axes, as manifested by resistance to dexamethasone and by disturbances in menstrual regularity or amenorrhea (Berger et al. 1983; Edelstein et al. 1983; Pirke et al. 1985). Consequently, these three syndromes present with evidence of increased HPA axis activation and disrupted HPG functioning and amenorrhea. The disturbances in LH secretion in anorexia nervosa and hypothalamic amenorrhea have been evaluated primarily by examining the characteristics of LH pulsatile activity. In anorexia nervosa, LH secretory patterns may revert to prepubertal levels of low nonpulsatile secretion or to a pubertal pattern of entrainment of LH secretion to the sleep cycle. Studies by Reame et al. (1985) in women with hypothalamic amenorrhea demonstrated that LH secretion in the follicular phase is slowed to the rate normally observed during the luteal phase. In these individuals, LH and FSH responses to GnRH appear normal, indicating that the reduced pulse frequency is not secondary to pituitary changes but presumably due to changes in the GnRH pulse generator. Figure 7–2 summarizes the various levels at which hormones of the HPA axis may impinge on the reproductive axis. Despite suggestions that reproductive hormones may play a role in mood disorders, the HPG axis has received little examination in depression.

Reproductive Abnormalities in Depression

In depression, response to GnRH has been assessed by several groups. Some studies have reported a normal LH and FSH response to GnRH in pre- and postmenopausal women (Unden et al. 1988; Winokur et al. 1982). However, given the major differences in LH pulse amplitude and mean LH levels between follicular and luteal phases, it would be extremely difficult to observe a difference in basal LH secretion between major depression and control women without strict control of menstrual cycle phase. However, Brambilla et al. (1990) noted a decreased LH response to GnRH in both premenopausal and postmenopausal women, with lower baseline LH concentrations in postmenopausal depressed women. It may be that the increased secretion of LH following removal of the negative feedback of gonadal steroids in postmenopausal women unmasks a decrease in LH secretion that is not as easily observed in women with intact estrogen and progesterone feedback. Other studies examining depressed patients of both sexes, which were not analyzed separately, observed no change in baseline or GnRH-stimulated LH and FSH secretion (Unden et al. 1988).

Only recently have studies begun to focus on the pulsatile rhythm of LH secretion in women with major depression. Thus far, there have been only four published studies examining pulsatile LH secretion in depressed women: two by Meller et al. (1997, 2001), a third by us (Young et al. 2000b), and a fourth looking at the data from both Meller and Young with spectral analysis (Grambsch et al. 2004). The data from the Meller studies showed slower LH frequency in the follicular phase. Our data revealed significantly lower estradiol in the follicular phase in a small sample of depressed women. Since our publication in December 2000, a large-scale epidemiological study by Harlow et al. (2003) has found that earlier menopause is accompanied by lower estradiol in perimenopausal depressed women. Thus, three recent carefully done studies using modern techniques with sophisticated analyses have found evidence of reproductive axis abnormalities in depressed women. One study of the reproductive axis in men with major depression (Schweiger et al. 1999) also revealed decreased testosterone and a trend for slower LH pulses, suggesting that abnormalities in the reproductive axis are also found in men. Consequently, further studies on the reproductive axis in depression are indicated.

Estrogen and Depression

Because of increased incidence of depression at critical hormonal transition phases such as postpartum and perimenopause, much speculation has taken place about estrogen's role as a precipitant. Recent studies have found increased incidence of depressive symptoms and major depression during the menopause transition (Cohen et al. 2006; Freeman et al. 2006). The initial findings of Freeman et al. (2004) in regard to estrogen were that both high and low estrogen levels were associated with depression. More recently, the data suggest that variability in estrogen levels may drive depression. A model of differential sensitivity to estrogen has been proposed for premenstrual dysphoric disorder (PMDD) and also by Cohen et al. (2006) to explain the findings of increased depression during the menopause transition. Increased FSH, suggesting ovarian aging, and overall low or variable estrogen were also found to be strongly associated with depression (Freeman et al. 2006). And in the Freeman et al. study, PMDD was associated with depression during the menopause transition. Furthermore, the central effects of estrogen are intriguing and lend credence to a possible role of estrogen in modulating critical neuronal systems involved in depression. Studies in nonhuman primates have confirmed that estrogen increases tryptophan hydroxylase, the rate-limiting step in serotonin synthesis (Bethea et al. 2002). Estrogen also decreases serotonin$_{1A}$ (5-HT$_{1A}$) autoreceptor binding, which would serve to increase serotonin levels at the synapse (Bethea et al. 2002). Estrogen modulates the serotonin transporter, leading to decreases in the transporter mRNA but increases in the transporter expression in the hypothalamus (Bethea et al. 2002). Estrogen also decreases monoamine oxidase A activity, which would potentiate actions of norepinephrine in the synapse, and increases tyrosine hydroxylase, the critical first enzyme for synthesis of norepinephrine (Bethea et al. 2002). However, use of estrogen as a treatment has produced mixed results, perhaps because not all studies have targeted women with changing estrogen levels. Early studies found an effect of high-dose estrogen augmentation on response to antidepressants (Klaiber et al. 1979; Shapira et al. 1985). In situations of recent-onset estrogen deficiency such as postpartum and perimenopause, estrogen has been demonstrated to be an effective treatment for depression in randomized, controlled trials (Gregoire et al. 1996; Schmidt et al. 2000; Soares et al. 2001). However, randomized, controlled trials examining the effects of estrogen on mood in postmenopausal women have been negative (Hlatky et al. 2002; Morrison et al. 2004), suggesting a loss of beneficial mood response to estrogen following prolonged periods without estrogen. Finally, if data on estrogen's role in *inhibiting* the HPA axis in normal women are correct, then lower estradiol in depressed women would result in exacerbation of the HPA axis abnormalities seen in major depression, and these may need to be corrected along with changing the ovarian hormone milieu.

Premenstrual Dysphoric Disorder

One of the most well-studied mood disorders, with respect to the influence of ovarian steroids on mood, is PMDD. In any studies of this disorder, it is necessary to define carefully the study population and limit both endocrine investigations and treatment to women with clear luteal phase depressive symptoms who are well during the follicular phase; many more women report significant variations in mood premenstrually in retrospective reports than are found to have symptoms with prospective studies. In a study that used optimal sampling frequency to investigate LH and FSH, pulse frequency, and amplitude in follicular, midluteal, and late luteal phases of the menstrual cycle and examined estradiol and progesterone levels at these three time points, there was no difference between estradiol and progesterone at any time point between women with PMDD and control women (Reame et al. 1992). LH pulse frequency was also similar in both groups, with parallel changes across the menstrual cycle. Thus, these and earlier data (Rubinow et al. 1988) do not suggest an alteration in GnRH secretion or ovarian steroids in women with PMDD. Nevertheless, several studies have suggested that hormone manipulations can improve the symptoms.

One of the best-documented effective treatments is elimination of menstrual cycling with leuprolide, a

GnRH agonist that improves mood. A number of studies found that leuprolide was highly effective in reducing symptom severity and cyclicity in PMDD patients (Mortola et al. 1991; Rosenbaum et al. 1996; Schmidt et al. 1998), although an increased rate of depressive-like symptoms has also been reported during leuprolide treatment (Steingold et al. 1987; Zorn et al. 1990). Leuprolide also leads to hypoestrogenism, which affects both bone density and cardiovascular disease; thus, it is necessary to add both steroid hormones. In the study by Mortola et al. (1991), just the addition of a placebo, with the suggestion that it might make mood symptoms worse, caused a significant worsening in mood symptoms. However, addition of conjugated equine estrogen with or without medroxyprogesterone acetate (MPA) while patients were still on leuprolide did not lead to a relapse in depressive symptoms. Not all studies have agreed that progesterone can be added back without significant worsening of symptoms. Schmidt and colleagues studied a group of women with PMDD whose symptoms were significantly improved by leuprolide, as well as a group of control women with no previous mood symptoms who were also taking leuprolide. They demonstrated a return of symptoms following administration of estradiol or progesterone but not with placebo. In the control women, none of the hormone replacements altered mood (Rubinow and Schmidt 2006). Finally, progesterone itself has been used for the treatment of PMDD despite its documented lack of effectiveness. The results of a recent Cochrane Database review of 17 randomized, placebo-controlled trials were equivocal, and the authors were unable to determine whether progesterone was useful or ineffective in the treatment of PMDD. They concluded that there was not enough evidence to say whether progesterone was helpful or ineffective (Ford et al. 2006).

Since it is generally believed that the symptoms of PMDD are related to delayed effects of progesterone on mood, several studies have investigated the effects of RU486, a progesterone antagonist, on mood symptoms. In the studies of Schmidt et al. (1991), creation of an artificial follicular phase during the second half of the menstrual cycle by the use of RU486 plus human chorionic gonadotropin did not result in a reduction of mood symptoms. Likewise, blockade of progesterone's action led to early menses, with depressive symptoms still occurring. The study by Chan et al. (1994), using a randomized, double-blind, placebo-controlled crossover design for 6 months, showed no effectiveness of RU486 on mood symptoms. Thus, although it is generally believed that PMDD is related to changes in CNS neurotransmitter systems caused by progesterone, the data do not support the conclusion that progesterone blockade affects these mood symptoms. Rubinow and Schmidt (2006) have proposed that PMDD represents an abnormal response to normal hormone changes or levels that occurs in a small proportion of genetically susceptible women and is most likely associated with gene polymorphisms involved in the gonadal steroid signaling pathway.

Another period of increased vulnerability to depression in women is the postpartum period. Although it is known that this period is accompanied by a sudden drop in progesterone and estradiol levels, there is limited information available on how this relates to the onset of depression. Postpartum depression is associated with a history of depression (O'Hara 1986; O'Hara et al. 1991), marital disharmony, and a higher number of stressful life events in the previous year (Cox et al. 1982). Gregoire et al. (1996) reported that transdermal estrogen is an effective treatment for depression. However, the group of women studied was small, heterogeneous, and ill-defined, and no information was available on whether these women had a new onset of depression or a prior psychiatric history. Furthermore, some of the patients were being concurrently treated with antidepressants.

GROWTH HORMONE AND THE HYPOTHALAMIC-PITUITARY-SOMATOTROPHIC AXIS

Growth hormone (GH) or somatotropin is another stress-sensitive neuroendocrine system. GH is synthesized by the anterior pituitary, and although it can be used as an endpoint in itself for neuroendocrine research in psychiatry, its predominant use is as a marker of the integrity of the noradrenergic system following challenge. The hypothalamic-pituitary-somatotrophic (HPS) axis is under complex regulatory control that is not yet fully understood since cross-species variations in GH

regulation make it difficult to extrapolate to humans from animal studies. It is well established, however, that the final common pathways for control of GH release from the pituitary are hypothalamic growth hormone–releasing hormone (GHRH) (stimulation) and somatostatin (inhibition). The wide variety of metabolic, endocrine, and neural influences that alter GH secretion do so primarily through effects on GHRH and/or somatostatin. Neural influences may be mediated by noradrenergic, cholinergic, dopaminergic, γ aminobutyric acid (GABA)–ergic, and serotonergic neurotransmission. Clear physiological regulatory roles, however, have only been well documented in humans for noradrenergic and cholinergic inputs. Dopamine, serotonin, and GABAergic drugs can alter GH release but do so in contradictory ways, depending on the experimental paradigm, leaving their roles as GH regulatory agents uncertain at present (Devesa et al. 1992; Muller 1987). In humans, GH is released by acute stress, but is suppressed by chronic stress. Chronic psychosocial stress in children can result in growth arrest and even short stature and delayed puberty. A variety of other endocrine, metabolic, and physiological factors can influence GH release, although the mechanisms by which they do so are not clear. Factors that can inhibit GH release include free fatty acids (Penalva et al. 1990) and, most importantly for this review, CRH (Corsello et al. 1992) and glucocorticoids (del Balzo et al. 1990; Giustina and Wehrenberg 1992). Studies by Wiedemann et al. (1991) examined GH secretion in healthy control subjects given hourly pulses of ACTH (1 μg) or h-CRH (10 μg) between 9 A.M. and 6 P.M. to induce hypercortisolemia. They found an increase in the number of GH pulses and amount of GH secreted during the daytime but did not find an increase in the total 8 A.M. to 3 A.M. GH secretion because of blunted nighttime secretion. This pattern is similar to that seen in depressed patients (Mendlewicz et al. 1985) who have increased daytime GH secretion and reduced sleep-related GH secretion, suggesting a similar mechanism may occur in depressed patients. However, our own studies of 26 premenopausal women with major depression and 26 age- and menstrual-cycle-day-matched control women examining 10-minute secretion of GH for 24 hours found no changes in GH secretion (Amsterdam et al. 1989).

Current evidence suggests that the normal episodic GH secretory pattern is shaped by an alternating rhythm of GHRH and somatostatin release (Plotsky and Vale 1985), which has been called the hypothalamic-somatotroph rhythm (HSR) (Devesa et al. 1992). This is not a regular alternation but consists rather of four to eight short pulses of GH secretion distributed irregularly over a 24-hour period, the largest one occurring shortly after the onset of sleep. The significant role of somatostatin in shaping the HSR is evidenced by its persistence in the face of a constant GHRH infusion (Hulse et al. 1986; Vance et al. 1985). The intrinsic HSR, in turn, appears to shape the response to exogenous GHRH (Devesa et al. 1989, 1990, 1991a, 1992; Tannenbaum and Ling 1984). The response is greatest if GHRH is given while plasma GH is rising or near the peak of a pulse, presumably indicating that somatostatin is suppressed. The GH response is minimal if GHRH is given while plasma GH is low and stable, presumably indicating predominance of the somatostatin effect. Currently available human data therefore suggest that clonidine exerts a major effect on GH release via suppression of somatostatin-mediated inhibition.

It appears that cholinergically mediated suppression of somatostatin plays a significant role in regulating nocturnal GH release (Ghigo et al. 1990; Mendelson et al. 1978; Peters et al. 1986). Factors that can enhance GH release include estrogen (Devesa et al. 1991b; Ho et al. 1987), thyroid-releasing hormone, vasoactive intestinal peptide, hypoglycemia, sleep, exercise, and stress (Devesa et al. 1992; Muller 1987; Uhde et al. 1992). Finally, GH exerts a negative feedback inhibition of its own secretion (Devesa et al. 1992; Muller 1987). It appears to act at the level of the hypothalamus and/or median eminence to stimulate somatostatin release (Devesa et al. 1992). It may also inhibit GHRH release (Devesa et al. 1992). GH also stimulates the production of somatomedin-C/insulin-like growth factor 1 (IGF-1) in peripheral tissues, including liver. Somatomedin-C in turn has a dual inhibitory feedback effect. It directly suppresses GH secretion at the pituitary level and stimulates somatostatin release at the hypothalamic level (Devesa et al. 1992). Levels of somatomedin-C correlate positively with, and

can be used to infer, systemic GH levels during the past 8–12 hours (Copeland et al. 1980; Ross et al. 1987; Vance et al. 1985). Measurement of somatomedin-C levels thus can provide another means of evaluating the overall functional status of the HPS axis.

Growth Hormone Studies in Psychiatric Disorders

Adrenergic input to the HPS axis is mediated primarily by the α_2-adrenergic receptor. α_2-Adrenergic agonism is a potent stimulus for GH secretion, the effect being blocked by corresponding antagonists (Devesa et al. 1992; Muller 1987). α-Adrenergic stimulation of GH release may also be antagonized by β-adrenergic agonism (Devesa et al. 1992), but the β-adrenergic-receptor-mediated influences are less well researched. In humans, the evidence suggests that the GH-releasing effect of α_2-adrenergic agonism may be due primarily to inhibition of somatostatin release, with perhaps a secondary stimulation of GHRH. This is based on two main types of evidence. First, for at least 2 hours after a supramaximal dose of GHRH (200 μg), the pituitary is refractory to a repeated dose of GHRH, but the α_2-adrenergic agonist clonidine (Valcavi et al. 1988) or insulin-induced hypoglycemia (Shibasaki et al. 1985) will still evoke a vigorous GH response. Presumably, if the GH-releasing cells are unresponsive to GHRH, clonidine must stimulate GH release through a non-GHRH mechanism, the most likely alternative being inhibition of somatostatin release. Similarly, insulin-induced hypoglycemia is thought to stimulate noradrenergic outflow, which then suppresses somatostatin secretion (Shibasaki et al. 1985). Whereas the GH response to GHRH depends on the point in the HSR rhythm at which the GHRH is given, the response to clonidine does not (Devesa et al. 1990, 1991a, 1992), again suggesting that clonidine acts through a non-GHRH mechanism, again presumably somatostatin.

Downregulation of GH release in response to clonidine presumably occurs in response to chronic, excessive noradrenergic outflow from the locus coeruleus, which is thought to play a role in anxiety states (Uhde et al. 1992). The blunted GH response to clonidine in panic disorder has been replicated in 8 of 10 studies from 6 of 7 different clinical research groups (Abelson et al. 1991, 1992; Amsterdam et al. 1989; Charney and Heninger 1986; Coplan et al. 1993; Nutt 1989; Schittecatte et al. 1988, 1992; Uhde et al. 1986, 1991). Both failures to replicate (Schittecatte et al. 1988, 1992) were by the same group. One of those studies (Schittecatte et al. 1988) involved only seven subjects, and blunting was absent only in the female subjects, in whom birth control pills or menstrual cycle phase can obscure blunting. Blunted GH response to clonidine is seen in generalized anxiety disorder (Abelson et al. 1991) and social anxiety disorder (Uhde et al. 1991) but not in obsessive-compulsive disorder (OCD) (Hollander et al. 1991; Lee et al. 1990). It has also recently been reported in patients with PTSD (Morris et al. 2004). It is unlikely that the GH blunting seen in anxiety disorders is an artifact of tricyclic exposure, given that in our own work, 10 of 12 anxiety patients with blunted responses had no significant prior exposure to tricyclic antidepressants (Abelson et al. 1992) and our recent findings demonstrate a blunted response in subjects with anxiety (predominantly social phobia) with no tricyclic exposure (Cameron et al. 2004). The nonspecificity of the GH response to clonidine suggests that it could be a secondary response to the presence of a psychiatric disorder. However, the absence of blunting in patients with OCD (Lee et al. 1990), schizophrenia (Lal et al. 1983), or heroin abuse (Facchinetti et al. 1985) argues against this interpretation. Although the replicability of the blunted GH response to clonidine in panic disorder is well established, the mechanism remains less certain. It has been thought to reflect subsensitivity (downregulation) of postsynaptic α_2-adrenergic receptors (Siever et al. 1982). Our own data support the presence of blunted GH response to clonidine in social anxiety disorder, suggesting that excessive noradrenergic tone is also present in this form of anxiety (Cameron et al. 2004). These data are consistent with the hypothesis that excessive noradrenergic outflow from the locus coeruleus plays a pivotal role in anxiety states (Charney and Heninger 1986).

Numerous studies have also demonstrated reduced GH responses to clonidine in patients with major and melancholic depression (Amsterdam and Maislin 1990; Amsterdam et al. 1989; Charney et al. 1982; Checkley et al. 1981; Corn et al. 1984; Lesch et al. 1988; Siever and Uhde 1984), but not all

studies have replicated these findings (Gann et al. 1995; Katona et al. 1993; Mitchell et al. 1991; Schittecatte et al. 1989, 1994). In particular, more recent studies have not found a blunted GH response to clonidine. It is unclear whether diagnostic changes and subject selection have affected these failures to replicate, given that several investigators found differences between endogenous and nonendogenous depression, with more severe blunting in the endogenous groups (Amsterdam et al. 1989; Checkley et al. 1984; Matussek and Laakmann 1981; Matussek et al. 1980). Furthermore, most of the studies in depression were done before it was realized that menstrual status (i.e., pre- vs. postmenopausal), menstrual cycle phase, and prior tricyclic exposure affected the GH response to clonidine. In particular, patients with endogenous depression are more likely to have been older and postmenopausal, both factors that decrease the GH response. The altered GH response to clonidine is thought to result from α_2-noradrenergic receptor downregulation, since studies using either GHRH, which acts directly at the pituitary, or apomorphine, which acts via dopamine input to the GH system, demonstrate normal GH response in depressed patients (Amsterdam and Maislin 1990; Corn et al. 1984; Krishnan et al. 1988; Lesch et al. 1988; Thomas et al. 1959). Again, this is consistent with increased central noradrenergic activation in depression, similar to that hypothesized in panic disorder. Our own recent studies (Cameron et al. 2004) found a normal GH response to clonidine in patients with "pure" depression (i.e., patients who did not meet criteria for any anxiety disorders). All of our patients had been off any psychotropic drugs for at least 6 months. Furthermore, there was no relationship between dimensional measures of anxiety or dimensional measures of depression and GH response. Patients with melancholic depression did not differ from nonmelancholic patients or control subjects. Subjects with a high Hamilton Anxiety Scale (Ham-A) score ($\geq$20, *n* = 13) did not differ from their matched controls. Thus, our data suggest that blunted GH response to clonidine challenge is specific to anxiety disorders and is not seen with less severe forms of anxiety or with depression in the absence of an anxiety disorder.

CONCLUSION

In this chapter we have reviewed ways in which hormonal systems may be altered in psychiatric disorders that may be linked to the pathoetiology of the disorders. The evidence is strongest for the HPA system, which has been implicated in at least two disorders, depression and PTSD, both disorders clearly linked to stress-based etiologies. The evidence for abnormalities in reproductive hormones is still small, but this is a subject of continued investigation. Most notably, abnormalities of reproductive hormones have not been found in PMDD, the disorder most responsive to changing reproductive hormone milieu. Finally, hormones can be used as markers of the functioning of CNS neurotransmitters or receptors, as is the case for GH. As neuroimaging ligands are developed to directly measure these receptors, the latter role of neuroendocrinology may be useful. Many of the critical hormones, like cortisol and estradiol, regulate many other critical neurotransmitter systems, such as serotonin, as well as regulating gene transcription. The area of psychoneuroendocrinology continues to expand, and in combination with the major advances occurring throughout the field of psychiatry, it will become possible to identify the genetic and molecular mechanisms involved in psychiatric disorders, thereby leading to the development of better treatments.

PRINCIPLES OF PHARMACOKINETICS AND PHARMACODYNAMICS: INTRODUCTION

Pharmacokinetics **is defined as the study of the time course of drugs and their metabolites through the body.** ***Pharmacodynamics*** **is defined as the study of the time course and intensity of pharmacological effects of drugs. A convenient lay description of these terms is that pharmacokinetics describes what the body's physiology does to a drug, and pharmacodynamics describes what a drug does to the body. Although clinicians are more interested in drug effects than drug concentrations, these disciplines are closely connected. Pharmacokinetic and pharmacodynamic variability is a major determinant of the dose–effect relationship in patients (Figure 8–1). There is increasing recognition that genetic variability—in the form of polymorphic genes controlling the transcription of proteins involved in drug-metabolizing enzymes, drug transporters, and drug targets—is a substantial determinant of pharmacokinetic and pharmacodynamic variability. An integrated knowledge of these areas is essential in the drug development process and can be instrumental in individualizing dosage regimens for specific patients.**

FIGURE 8–1. Pharmacokinetic and pharmacodynamic variability as determinants of the dose–effect relationship.

The dose and the frequency of dosing necessary to produce the desired pharmacological response from psychoactive drugs differ widely among patients. This variability in the drug dose–effect relationship is not surprising, given the large differences in patients' physiology, ages, range of severity of illness, activity of drug metabolizing enzymes and transporters, renal function, and other variables. Thus, a rational approach to drug dosage regimens, based on scientific principles, is needed to reach therapeutic objectives without either underdosing (and obtaining an unsatisfactory response) or overdosing (and risking intolerability or toxicity).

The interface between pharmacokinetics and pharmacodynamics, where drugs interact with molecular targets at an effect site (see Figure 8–1), is increasingly becoming the focus of research. The ability to link drug concentrations with pharmacodynamic effects using mathematical models has improved greatly in recent years with the availability of new computer software. Population pharmacokinetic/pharmacodynamic modeling enables definition of the relationship between drug concentration and effect in individuals from vulnerable populations such as children, pregnant women, and the elderly where only sparse data may be available (Bies et al. 2004). Covariants such as age, gender, genotype of drug-metabolizing enzymes, and concomitant treatment with other drugs can be easily incorporated into these models and tested for their significance in influencing drug concentration and effects

(DeVane et al. 2006). Measurements of plasma drug concentration are easily performed with sensitive analytical methods including gas and liquid chromatography and mass spectrometry.

In recent years, our understanding of the role of drug transporters and of gene expression of intestinal and hepatic enzymes in influencing drug movement within the body has increased considerably. Extensive contributions to our understanding of the sources of variability in pharmacokinetic/pharmacodynamic response have come from the field of pharmacogenetics. Genetic polymorphisms in drug-metabolizing enzymes enhance or diminish the body's ability to biotransform a variety of substrate drugs. A large number of defective alleles have been discovered, some of which have functional significance. On the pharmacodynamic side of the dose–effect relationship, the significance of polymorphisms in drug targets is an intense area of investigation. One of the most studied polymorphisms is in the promoter region of the gene encoding the serotonin transporter (5-HTT) and consists of the insertion or deletion of a 44–base pair sequence, giving rise to two variants: long (l) and short (s). A meta-analysis of 15 studies representing 1,435 patients concluded that patients with the ss genotype are less likely to reach remission during selective serotonin reuptake inhibitor (SSRI) therapy and require a longer treatment period for 50% symptom improvement (Serretti et al. 2007).

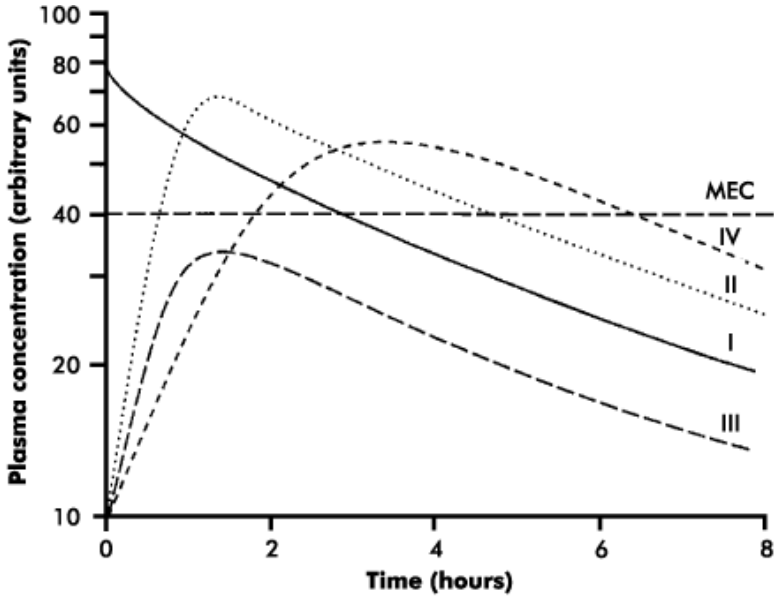
Although the discipline of pharmacokinetics relies heavily on mathematical description and prediction of the time course of drugs in the body, the purpose of this chapter is to explain basic principles of pharmacokinetics and how they interface with pharmacodynamics to provide insight into observed dose–effect relationships that can aid in developing drug dosage regimens. The fundamental concepts of pharmacokinetics have not changed since the initial publication of this chapter. These principles are reviewed here, and the interface of pharmacokinetics with the discipline of pharmacogenetics—the study of the genetic basis for differences in drug effects—is discussed as a essential component of variability in drug dose–effect relationships in psychopharmacology (see Figure 8–1).

PHARMACOKINETICS

A human pharmacokinetic study typically results in a mathematical description of drug concentration changes in plasma over time. The value of these data and of their use varies according to patient circumstances. During drug development, this knowledge is essential to develop guidelines for ensuring safe and effective dosage regimens in clinical trials. In clinical practice, plasma concentration measurements are useful to guide dosage adjustments to reach targeted steady-state concentrations of lithium, some anticonvulsant mood stabilizers, and clozapine. In the United States, the low utilization of tricyclic antidepressants and conventional antipsychotics has narrowed the scope of plasma drug concentration monitoring in psychiatry. However, a resurgence of interest is occurring as the search for biomarkers of drug efficacy and tolerability is increasing in drug development (Sunderland et al. 2005). Even without patient-specific drug concentration data, some knowledge of population pharmacokinetic parameters is clinically useful. Population estimates of drug and metabolite half-life can predict the time required for washout from the body once drug dosing is discontinued. This is useful for predicting the overlap of drug in the body when switching among antidepressants or antipsychotics, the presence of drug in the body during anesthesia for surgical procedures, and the probability of a drug–drug interaction when initiating new pharmacotherapy. Such information is useful when prescribing fluoxetine, for example, which produces an active metabolite, norfluoxetine, with an elimination half-life estimated between 4 and 16 days. Thus, an interval as long as 1 month may be necessary after discontinuing fluoxetine before initiating treatment with a monoamine oxidase (MAO) inhibitor to minimize the possibility of developing a serotonin syndrome. The use of slow-release microspheres for injection of risperidone results in an extended drug half-life that predicts continual accumulation to a steady state over four injections given every 2 weeks and sustained drug concentration in plasma for 4–6 weeks after the last injection (Gefvert et al. 2005). The fundamental description of drug disposition begins with studies of single drug doses.

Single-Dose Drug Disposition

Absorption



The route of administration is a major determinant of the onset and duration of a drug's pharmacological effects. Intravenous injection ensures that all of the administered drug is available to the circulation. The rate of drug injection or infusion can be used to control completely the rate of drug availability. However, few psychopharmacological drugs are administered intravenously. Intramuscular administration is commonly thought to produce a rapid onset of effect, but exceptions have been documented. For example, drug absorption by this route was slow and erratic with chlordiazepoxide (Greenblatt et al. 1974). The recent availability of intramuscular forms of some atypical antipsychotics will be advantageous for treating psychotic states when rapid tranquilization is desired and oral administration is impractical. For drugs that are equally well absorbed by the intramuscular and oral routes of administration, the total systemic exposure (as reflected in the area under the plasma concentration–time curve

[AUC]) from the two routes should be similar, as should the elimination half-life. A major difference is that the rate of absorption from the intramuscular route may be more rapid. Intramuscular administration of olanzapine 5 mg produced a maximum plasma concentration five times higher than the maximum plasma concentration produced by a 5-mg oral dose with a similar AUC from both routes of administrations (Bergstrom et al. 1999). Most psychoactive drugs are highly lipophilic compounds, which are well absorbed when taken orally. More than 60% of the drugs available on the market are for oral use because of the ease of administration and efficiency of absorption, together with greater patient compliance.

Drug absorption is usually a passive process occurring in the small intestine. The efficiency of oral absorption is influenced by the physiological state of the patient, by formulation factors, and by the timing of administration around meals. Most drugs are best absorbed on an empty stomach. The presence of food or antacids in the stomach usually decreases the rate of drug absorption. Exceptions are sometimes noted. Coadministration of sertraline with food increased peak plasma concentration by approximately 25% and decreased time to peak concentration from 8 hours to 5 hours, with a negligible effect on the AUC (Ronfeld et al. 1997). A partial explanation for this finding is that a food-induced increase in hepatic blood flow could allow more unabsorbed drug to escape first-pass hepatic uptake and metabolism. The significance of this food–drug interaction is doubtful, given that sertraline's therapeutic benefits are reported in association with chronic daily administration. The rate of drug absorption is important when a rapid onset of effect is needed. Normally, the presence of food can be expected to reduce the peak drug concentration achieved in blood or plasma and prolong the time following an oral dose to reach the maximum plasma concentration. The absolute amount of drug absorbed may or may not be affected. Acute drug effects are facilitated by administration apart from meals. Sedative-hypnotic drugs are examples of drugs for which the rate of absorption is clinically meaningful (Greenblatt et al. 1978).

Formulation factors are especially meaningful when a drug effect is associated with achieving a minimal effective concentration (MEC) in plasma. Figure 8–2 shows the predicted plasma concentration–time curves of a drug following a rapid intravenous injection (I), an oral formulation that is completely absorbed with no presystemic elimination (II), an incompletely absorbed oral formulation (III), and an extended-release formulation that results in slow absorption of drug (IV). A formulation with poor bioavailability (III) may not result in a plasma concentration above the MEC, whereas a drug whose absorption is delayed (IV) may retard the onset of effect but maintain an effective concentration for a period similar to the more rapidly available formulations (I, II). The principle of an MEC may apply in antipsychotic therapy, where minimal occupancy of dopamine D_2 receptors during a dosage interval may be needed for optimal therapeutic benefit.

FIGURE 8–2. MEC = minimal effective concentration.

Recent research in pharmaceutical science has resulted in a variety of systems for controlling the release of oral drugs. These include coated systems, with a core of active drug surrounded by a slow-releasing film; matrix systems, with active drug distributed in erodible gel matrices, and other hydrophilic, swellable, or erodible polymers to slowly dissolve and release drug at predictable rates to produce one or more peak concentrations during a dosage interval. Bupropion, paroxetine, venlafaxine, and the psychostimulants used to treat attention-deficit/hyperactivity disorder (ADHD) are examples of drugs whose clinical utility has been improved by reformulation as sustained- or extended-release dosage forms. Among the immediate-release dosage formulations, a general rank order of products providing the most rapid to the slowest rate of drug release for oral absorption is solutions, suspensions, tablets, enteric- or film-coated tablets, and capsules. Regardless of the dosage formulation selected, the last several hours of declining drug concentration in plasma occur in parallel, because drug elimination rate is unaffected by its rate or extent of absorption (see Figure 8–2). The time at which a terminal elimination phase is clearly observable following a single dose may be delayed, but the terminal elimination half-life is unchanged. Formulation into sustained- or slow-release tablets or capsules may allow drugs with short elimination half-lives, which must be given multiple times per day to maintain an effective concentration, to be effective when administered once or twice daily.

Presystemic Elimination

Many drugs undergo extensive metabolism as they move from the gastrointestinal tract to the systemic circulation (i.e., as they pass through the gastrointestinal membranes and hepatic circulation during absorption). This process is known as the *first-pass effect* or *presystemic elimination* and is an important determinant of drug bioavailability after oral administration. Several factors are potentially important in influencing the degree of first-pass effect. A first-pass effect is usually indicated by either a decreased amount of parent drug reaching the systemic circulation or an increased quantity of metabolites after oral administration compared with parenteral dosing. This process is important in the formation of active metabolites for psychoactive drugs and is a major source of pharmacokinetic variability (George et al. 1982).

Presystemic metabolism of drugs is extensively accomplished by cytochrome P450 (CYP) enzymes in the luminal epithelium of the small intestine (Kolars et al. 1992). CYP3A4 represents approximately 70% of total cytochrome P450 in the human intestine. Many useful psychopharmacological drugs are CYP3A4 substrates. Examples of these drugs are listed in Table 8–1 along with substrates, inhibitors, and inducers of other major human CYP isoforms. The liver contains about two- to fivefold greater amounts of CYP3A protein (nmol/mg protein) compared with the intestine (de Waziers et al. 1990). Nevertheless, intestinal CYP3A4 has a profound effect on presystemic drug metabolism. Up to 43% of orally administered midazolam, for example, is metabolized as it passes through the

intestinal mucosa (Paine et al. 1996). The exposure of drugs to gut CYP3A4 is not limited by binding to plasma proteins, as can occur with hepatic metabolism. Slower blood flow may also contribute to intestinal metabolism, thereby compensating for the lower quantity of CYP3A4 in the gut compared with the liver.

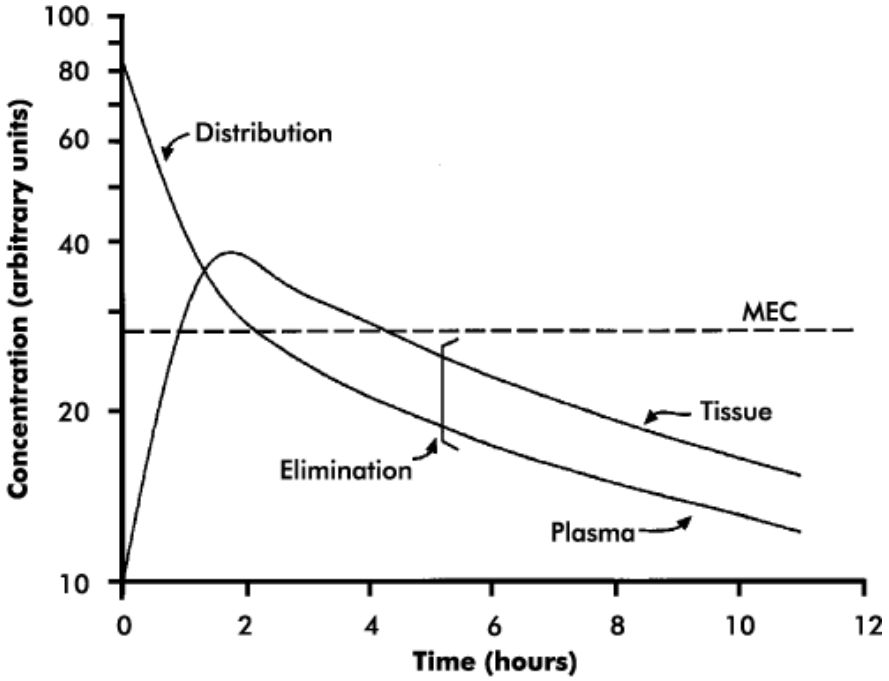
Certain foods, such as grapefruit juice, can substantially alter the bioavailability of some drugs. Components in grapefruit juice—which contains a variety of suspect candidates, including naringin, other flavonoids, bergamottin, and other furanocoumarins—inhibit intestinal CYP3A4-mediated first-pass metabolism (Paine et al. 2005). The maximal effect can occur within 30 minutes of ingestion of juice. Grapefruit juice may also inhibit the efflux transport of drugs by P-glycoprotein (P-gp) and multidrug resistance protein 2 (MRP2), which are efflux transporters expressed in the human small intestine. The more completely studied of these drug transporters is the transmembrane pump P-gp (also known as the multidrug resistance protein), which causes the adenosine triphosphate (ATP)–dependent efflux of a diverse range of drugs from cells. The distribution of P-gp includes the

epithelial cells lining the luminal surface of enterocytes in the small intestine and kidney, making P-gp a critical determinant of oral drug bioavailability and biliary and renal excretion for many drugs (Benet et al. 1999; Silverman 1999). P-gp is also expressed on the luminal surface of the endothelial cells making up the blood–brain barrier and other critical organs. In the gut, P-gp works in concert with CYP3A4 to limit the intestinal absorption of drugs that are common substrates for both proteins.

Changing the route of administration to avoid presystemic metabolism can have a therapeutic advantage. When given orally, selegiline, an irreversible inhibitor of MAO, is substantially converted to several metabolites through extensive first-pass metabolism. Transdermal dosing with drug contained in a removable patch adhering to the skin results in higher systemic exposure to selegiline and lower exposure to metabolites. This allows greater central nervous system (CNS) exposure to selegiline from a given dose to inhibit MAO relative to the required dose from oral administration (Azzaro et al. 2007). Buccal or sublingual administration can also avoid some presystemic drug elimination (Markowitz et al. 2006).

In summary, an important pharmacokinetic principle is that the choice of drug formulation and the route of administration can determine the rate at which the drug and metabolites appear in the systemic circulation. This rate may be manipulated to retard the magnitude of the peak plasma drug concentration when a high peak concentration is related to the occurrence of adverse effects. For example, slow-release formulations of lithium and paroxetine reduce gastrointestinal side effects (DeVane 2003). Alternatively, rapid absorption may be desirable to achieve immediate pharmacological effects.



Distribution

Drug distribution to tissues begins almost simultaneously with absorption into the systemic circulation. The rate at which distribution occurs will partially influence the onset of pharmacological response. Access to effect sites depends on membrane permeability, the patient's state of hydration, regional blood flow, and other physiological variables. There is increasing evidence that drug transporters in the blood–brain barrier influence drug passage to and accumulation in the brain. Sadeque et al. (2000) demonstrated that loperamide, a potent opiate used to reduce gut motility and not normally distributed to the CNS, produced typical opiate depressant effects on respiratory drive when coadministered with quinidine, a P-gp inhibitor. Physicochemical properties influencing the rate of drug distribution to effect sites include lipid solubility, ionizability, and affinity for plasma proteins and tissue components. Diazepam is highly lipophilic, and its onset of effect is rapid as a result of its entry into the brain within minutes after oral administration (Greenblatt et al. 1980). The concentration of diazepam at its effect site may fall so precipitously as a result of redistribution that its duration of action after an initial dose is shorter than would be expected based on its elimination half-life.

Frequently, the intensity and duration of the pharmacological effect of a second drug dose, taken immediately after cessation of the effect of the first dose, are greater and longer, respectively, than the intensity and duration of the effect of the first dose. This is known as the *second-dose effect* in pharmacokinetics (DeVane and Liston 2001). When dosing is repeated before the previous dose has been eliminated from the body, the second and subsequent doses produce a greater effect than the initial dose, but the relative intensity of subsequent doses diminishes. This second-dose effect occurs, regardless of the half-life of the drug, when dosing is repeated in response to the observed effect. Common examples of this phenomenon include the self-administration of caffeine and the administration of certain anesthetics.

The predicted time course of drug concentration in plasma and in tissue following a single intravenous drug injection is shown in Figure 8–3. Drug concentration in plasma rapidly declines in a manner consistent with the extensive distribution of the compound out of the systemic circulation. Drug concentration in tissue rapidly increases during this time. Pharmacological effects may not occur immediately but may be delayed until the tissue concentration at the effect site rises above an MEC. An equilibrium eventually occurs between drug in plasma and in tissue. Concentrations from this time forth decline in parallel during a terminal elimination phase.

MEC = minimal effective concentration.

The observed time course of drug concentration changes in plasma has frequently been considered in the pharmacokinetic literature to confer the characteristics on the body of a two-compartment mathematical model (Gibaldi and Perrier 1975). Many drugs appear to be absorbed into a central compartment composed of the circulation and rapidly equilibrating tissues and then distributed to less accessible tissues, which collectively form a peripheral compartment. This compartmentalization of drug concentration greatly aids mathematical analysis of pharmacokinetic data but is clearly an oversimplification, because drug concentrations determined in animal studies can vary over orders of magnitude among different tissues (DeVane and Simpkins 1985).

Even though the drug concentration can vary widely among tissues, equilibrium eventually occurs between drug concentration in plasma and in tissue (see Figure 8–3). The concentration of drug in brain tissue may be substantially different—higher or lower—from that in plasma, but renal and hepatic elimination of drug from the central compartment reducing the plasma drug concentration should be mirrored by a proportional reduction of drug concentration from the brain or other tissues. For this reason, an MEC determined from plasma data may reflect an MEC at the effect site. The distribution of a drug in the body largely depends on the drug's relative binding affinity to plasma proteins and tissue components and the capacity of tissues for drug binding. This pharmacokinetic principle is illustrated in Figure 8–4. Only unbound drug is capable of distributing between plasma and tissues. Different degrees of plasma protein binding among antidepressants, for example, cannot be used to draw valid conclusions about the availability of drug to exert pharmacological effects at the site of action (DeVane 1994). The nonspecific binding of drugs to tissue components complicates the interpretation of the significance of plasma protein–binding differences among drugs. Drug binding in tissues cannot be measured directly in vivo and must be inferred using mathematical models and/or in vitro methods.

FIGURE 8–4. Effect of protein binding on distribution of drug between plasma and tissue.

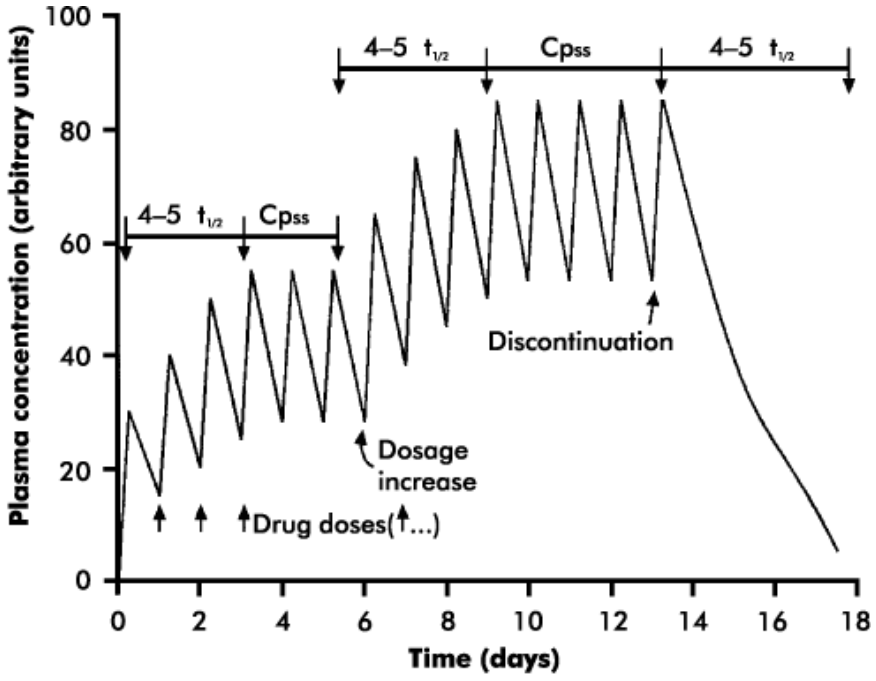
Most drugs circulate in the blood bound to plasma proteins, principally albumin or alpha-1-acid glycoprotein. Many psychotropic drugs are highly protein bound, frequently to a degree greater than 90%. Displacement of drug from plasma protein–binding sites may result from drug–drug interactions. This situation should lead to more unbound drug being available for distribution to peripheral tissues and interaction with receptor sites (see Figure 8–4). As a result, potentially greater pharmacological effects, either beneficial or detrimental, may be expected. However, there are few documented examples in which the above events occurred with psychoactive drugs and led to significant clinical consequences. Compensatory changes occur in the body to buffer the impact of drug-binding interactions (DeVane 2002). When plasma protein binding is restrictive regarding the drug's hepatic and/or renal elimination, the increased free drug concentration in plasma will be a transient effect as more free (non-protein-bound) drug becomes available to routes of elimination. Total (bound plus free) drug concentration in plasma will eventually return to a predisplacement value. The conclusion of several authoritative reviews is that plasma protein–binding displacement interactions are rarely a major source of variability in psychopharmacology (DeVane 2002; Greenblatt et al. 1982; Rolan 1994; Sellers 1979).

Elimination

Drugs are eliminated or cleared from the body through renal excretion in an unchanged or conjugated form; through biotransformation, primarily in the liver, to polar metabolites; or through both of these mechanisms (see Figure 8–1). *Clearance* is defined as the volume of blood or other fluid from which drug is irreversibly removed per unit of time. Thus, clearance units are volume per time. Drug clearance is analogous to creatinine clearance by the kidney. From the blood that delivers drug to the liver, or any other eliminating organ, an extraction occurs as blood travels through the organ. Because drug extraction by the liver and other organs is rarely 100%, the portion that escapes presystemic elimination reaches the systemic circulation intact. Plasma protein binding, as mentioned above, can restrict the organ extraction process, depending on the specific drug. If a drug were to be completely extracted, then clearance would equal the blood flow to the organ. An average hepatic blood flow is 1,500 mL/minute. When drug is eliminated by additional organs, the total clearance is an additive function of all the individual organ clearances. Clearance values reported in excess of 1,500 mL/minute for many psychopharmacological drugs are reflective of presystemic elimination (DeVane 1994). When the drug dose and bioavailability are constant, then clearance is the pharmacokinetic parameter that determines the extent of drug accumulation in the body to a steady state. In contrast, elimination half-life is useful to reflect the rate, but not the extent, of drug accumulation.



***Elimination half-life* is defined as the time required for the amount of drug in the body, or drug concentration, to decline by 50%. This parameter is commonly determined after a single-dose pharmacokinetic study or after drug discontinuation in a multiple-dose study. In either situation, drug concentration decline in plasma can be followed by multiple blood sampling. Half-life is easily determined by graphical means or by inspection, as long as data are used from the terminal log-linear portion of the elimination curve (see Figures 8–2 and 8–3). Knowledge of a drug's elimination half-life is particularly useful for designing multiple-dosing regimens.**

Multiple Dosing to Steady State

Multiple drug doses usually are required in the pharmacotherapy of mental illness. During a multiple-dosing regimen, second and subsequent drug doses are usually administered before sufficient time has elapsed for the initial dose to be completely eliminated from the body. This process results in drug accumulation, as illustrated in Figure 8–5. When drug elimination follows a linear or first-order process, the amount of drug eliminated over time is proportional to the amount of drug available for elimination (Gibaldi and Perrier 1975). Accumulation does not occur indefinitely; rather, it reaches a steady state. A *steady state* exists when the amount of drug entering the body is equal to the amount leaving the body. From a practical standpoint, this definition means that after a period of

continuous dosing, the body retains a pool of drug molecules from several doses, and the drug eliminated each day is replaced by an equivalent amount of newly administered drug. The time required from the first administered dose to the point at which an approximate steady state occurs is equivalent to the total of four to five elimination half-lives. The same amount of time is required for a new steady state to be achieved after an increase or decrease in the daily dosing rate or for a drug to wash out of the body after dosing is discontinued (see Figure 8–5).

FIGURE 8–5. Accumulation of drug during multiple dosing.

It takes four to five half-lives (4–5 $t_{1/2}$) to achieve initial steady state (Cp_{ss}) on a constant dosage regimen, to achieve a new steady state after an increase in dosage, or to wash out drug from the body after discontinuation. The average steady-state concentration lies somewhere between the peaks and troughs of drug concentration during a dosage interval.

The term *steady state* is a misnomer in that a true drug steady state occurs only with a constant-rate intravenous infusion. Because of the concurrent processes of drug absorption, distribution, and elimination, drug concentration is constantly changing in plasma and tissues during an oral dosing regimen. A peak and a trough concentration occur within each dosage interval. The average steady-state concentration occurs somewhere between these extremes and is determined by the daily dose and the drug's total body clearance for that individual.

On reaching a steady-state concentration, the average concentration and the magnitude of the peaks and troughs may be manipulated according to established pharmacokinetic principles. Figure 8–6 shows the predicted plasma concentration changes based on drug doses given every 24 hours. The selected dose does not produce a high enough average steady-state concentration to reach the desired concentration range between an MEC and a concentration threshold associated with an increased risk of toxicity. By doubling the dose and keeping the dosage interval constant, the average steady-state concentration increases, but the magnitude of the peak and trough concentration difference also increases. These changes are consistent with the pharmacokinetic principles of superposition and linearity (Gibaldi and Perrier 1975).

FIGURE 8–6. Predicted plasma concentration changes from administering either a selected dose (D) every 24 hours (D q24h), twice the dose every 24 hours (2D q24h), or the original dose every 12 hours (D q12h).

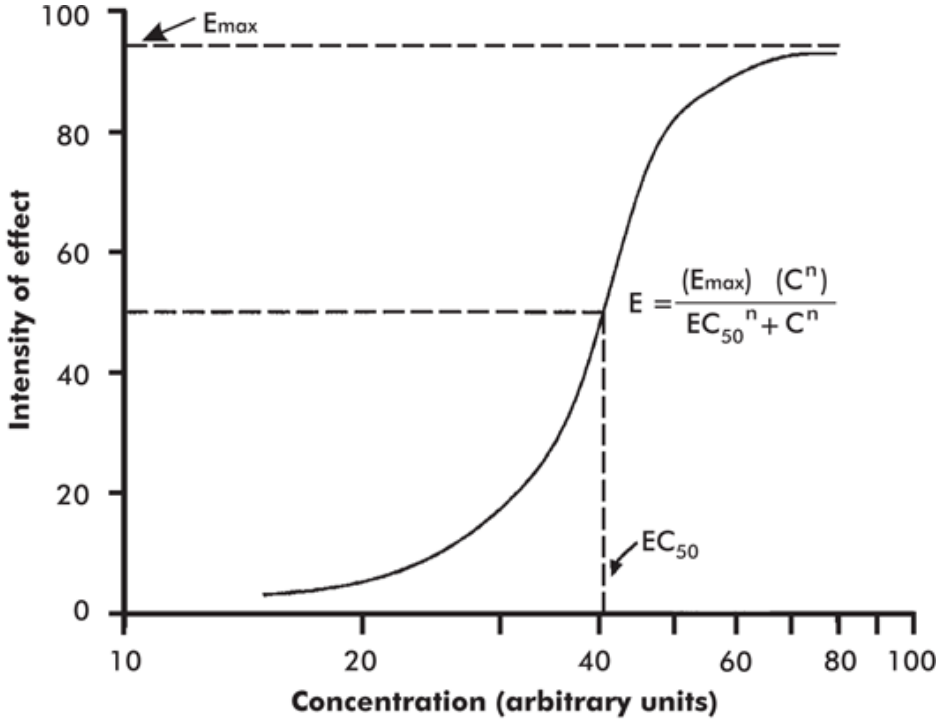
MEC = minimal effective concentration.

Linearity **refers to maintaining a stable clearance across the usual dosage range. Within the linear dose range, the magnitude of a dosage increase results in a proportional change in steady-state concentration (see Figure 8–6). The magnitude of the dose change theoretically superimposes on the new peak and trough concentration. In Figure 8–6, doubling the daily dose results in an adequate average steady-state concentration, but the new peak and trough concentration values cause both an increased risk of toxicity and an inadequate concentration declining below the MEC for a portion of each dosage interval. An alternative is to increase the total daily dose and divide it into more frequent administrations. This is accomplished by administering the original dose every 12 hours instead of every 24 hours. The new average steady-state concentration remains within the desired range, and the differences between the peak and trough concentrations are reduced to an acceptable fluctuation.**

Selection of a proper drug dosage regimen must consider both the amount of drug administered and the frequency of administration. Some drugs with half-lives long enough to be administered once daily may not be suitable for administration every 24 hours because toxicity may be precipitated by an excessive peak concentration in a single dose. Examples include lithium and clozapine. Once-daily dosing with lithium may produce gastrointestinal intolerance, and clozapine is dosed two or more times each day to avoid peak concentrations that might predispose to seizure activity. Bupropion was initially formulated to be dosed multiple times a day to avoid high peak concentrations in plasma for this same reason but reformulation into an extended-release tablet allows once-daily administration. When high peak concentration is tolerable, then the dosage interval can theoretically be extended beyond 1 day by giving larger amounts of drug in single doses less frequently. This principle applies to fluoxetine, which is available as a 90-mg capsule for once-weekly administration.



PHARMACODYNAMICS

Pharmacodynamic variability may exceed pharmacokinetic variability (see Figure 8–1). The drug dose or concentration that produces a pharmacological effect differs widely among patients. Similarly, pharmacological effects can vary widely among patients with a comparable plasma concentration of drug.

The principles of dosage regimen design discussed above rely heavily on the existence of a functional relationship between the concentration at an effect site and the intensity of the response produced. Many observed processes in nature behave according to the sigmoid relationship shown in Figure 8–7. At a low dose or concentration, only a marginal effect is produced. As drug dose or concentration increases, the intensity of effect (E) increases until a maximum effect (E_{max}) is achieved. This response is observed as a plateau in the sigmoid dose–effect curve (see Figure 8–7). Further dosage increases do not produce a greater effect.

FIGURE 8–7. The sigmoid maximum effect (E_{max}) pharmacodynamic model relates concentration (C) to intensity of

effect (E).

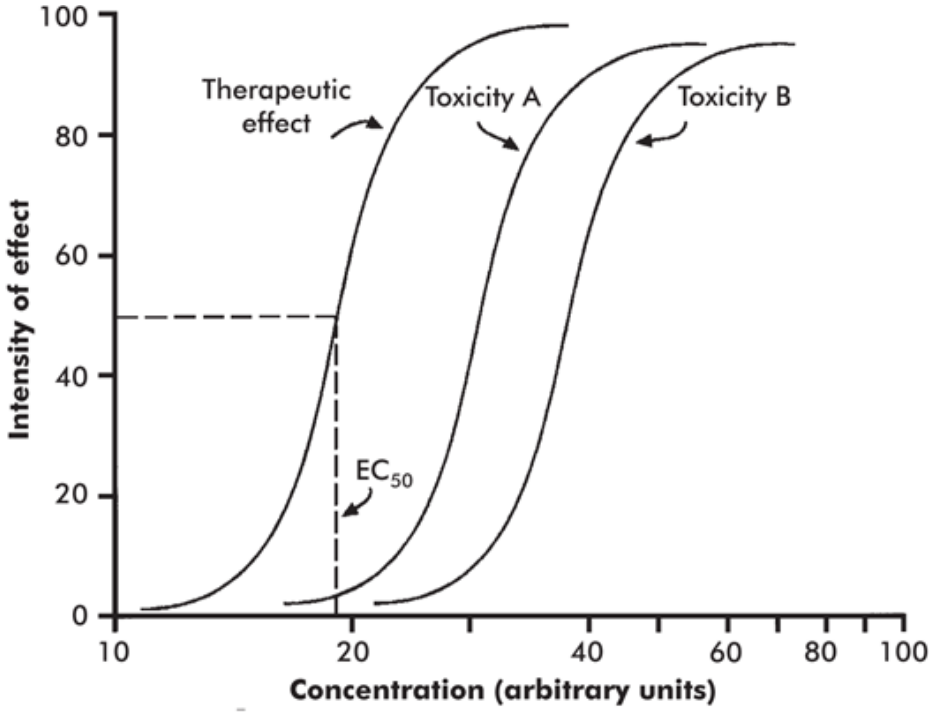
EC_{50} is the concentration that produces half of the E_{max}, and *n* is an exponent that relates to the shape of the curve.



The sigmoid dose–effect relationship in Figure 8–7 has practical applications to psychopharmacology. The increase in drug response that results from an increase in dosage depends on the shape and steepness of the theoretical dose–response curve for each patient and the starting point on the curve when a dosage is changed. At low doses or concentrations, a substantial dose increase may be necessary to achieve an effect. In a linear part of the relationship, dosage increases should result in proportional increases in effect. In the higher dose or concentration range, a further increase will not produce a significant increase in effect because of diminishing returns. This phenomenon is likely caused by the saturation of enzyme-binding sites or receptors by drug molecules above a critical concentration.

The general equation shown in Figure 8–7 describes the sigmoid relationship between concentration and response (i.e., intensity of effect). The response is usually measured as a percentage change or the difference from the baseline effect. C is the drug concentration, and EC_{50} is the effective concentration that produces half of the E_{max}. Theoretically, *n* is an integer reflecting the number of molecules that bind to a specific drug receptor. Practically, it is a parameter that determines the sigmoid shape of the concentration–effect relationship. Pharmacokinetic–pharmacodynamic models have found wide application in psychopharmacology—for example, relating concentration to electroencephalogram parameters, psychomotor reaction times, and subjective effects from drugs of abuse (Dingemanse et al. 1988).

Drugs rarely have a single pharmacological effect or interact with only a single receptor population or molecular target. Drugs generally have affinity for multiple receptors; therefore, several theoretical concentration–effect relationships can exist for a given drug. Dose–response curves are shown in Figure 8–8 for a drug that produces a therapeutic effect and mild and severe toxicity. The greater the separation between the curves for therapeutic and toxic effects, the more safely the drug can be administered in increasing doses to achieve therapeutic goals. Estimates of these interrelationships are made in preclinical animal studies and Phase I human studies for drugs in development. In clinical practice, the degree of separation between these curves and their steepness will show both inter- and intraindividual variability. Concurrent medical illness may predispose patients to side effects by effectively causing a shift to the left in one or both of the concentration–toxicity curves. This narrows the range over which doses can be safely administered without incurring adverse effects. The EC_{50} in Figure 8–8 produces

negligible toxicity. Increasing the concentration with a dosage increase to gain an increased response can only be accomplished at the expense of mild toxicity. As the dosage and concentration increase, therapeutic effects approach a plateau, and small increments in concentration result in a disproportionate change in toxicity.

The concentration is shown for a therapeutic effect that produces 50% of the maximum effect (EC_{50}).

The pharmacodynamic relationships considered above are most reproducible when pharmacological effects are direct and closely related to plasma concentration. In Figure 8–9, the concentration–effect relationship is shown as a function of drug concentration changes over time. In Figure 8–9A, the changes in effect are almost superimposable with the increase and decrease in concentration. This type of relationship often reflects a direct action of the drug with a single receptor. This straightforward relationship is generally not observed in psychopharmacology.

Drug concentration changes occur in the direction of the arrow. Effects superimposable on concentration changes **(A)** suggest a direct and reversible interaction between drug and receptor, a clockwise hysteresis curve **(B)** suggests the development of tolerance, and a counterclockwise curve **(C)** suggests an indirect effect or the presence of an active metabolite.

In Figure 8–9B, the response has begun to diminish with time before concentration begins to decline. This type of plot is known as a *clockwise hysteresis curve.* The observed effect may be explained by the development of tolerance. The time course of tolerance to psychoactive drug effects varies from minutes to weeks. Acute tolerance to some euphoric effects of cocaine can occur following a single dose (Foltin and Fischman 1991). Tolerance to the sedative effects of various drugs may take weeks. The mechanisms operative in the development of tolerance include acute depletion of a neurotransmitter or cofactor, homeostatic changes in receptor sensitivity from blockade of various transporters, or receptor agonist or antagonist effects. Ultimately, cellular responses to chronic treatment with drugs can alter gene transcription factors as mediators of physical and psychological aspects of tolerance (Nestler 1993).

A time delay in response occurs when effects are increasing and are maintained despite decreasing plasma drug concentration (see Figure 8–9C). This results in a *counterclockwise hysteresis curve*. A pharmacokinetic explanation of this lag in response may involve a delay in reaching the critical drug MEC at the effect site until the plasma concentration has already begun to decline. Alternatively, response may depend on multiple "downstream" receptor effects. This theory likely accounts for the counterclockwise hysteresis curve observed between plasma drug concentration and growth hormone response in plasma after an intravenous alprazolam challenge (Osman et al. 1991). Response may increase despite a decreasing drug concentration when a metabolite contributes to the observed effects. To overcome these complications, kinetic dynamic models can incorporate an "effect"

compartment (see Figure 8–1). The effect site equilibrates with plasma after a finite time, which can be assigned a half-life. Models can also incorporate the presence of metabolites (Dingemanse et al. 1988).

VARIABILITY IN THE DOSE–EFFECT RELATIONSHIP

A major challenge of treating mental illness with drugs is that both pharmacokinetic and pharmacodynamic variability complicate the dose–effect relationship. The presence of active metabolites, the influence of pharmacogenetics, and the effects of combining two or more drugs contribute to variability. Noncompliance with the prescribed treatment plan on the part of the patient can seriously undermine reliability in the expected effects from pharmacotherapy. Physiological differences between patients are another source of variability. The effects of age, weight, and hepatic and other disease states are major factors in pharmacokinetics and pharmacodynamics that indicate the need for individualization of therapy.

Active Metabolites

With the exceptions of lithium and gabapentin, which are renally excreted, drugs used in clinical psychopharmacology are cleared partially or completely by metabolism, primarily in the liver. Many psychoactive drugs produce pharmacologically active metabolites that distribute to the effect sites (see Figure 8–1) to produce pharmacological effects. Like their precursors, metabolites may have multiple pharmacological effects that may be similar to or different from those of the parent drug. Sertraline's metabolite, desmethylsertraline, has about 10% of the activity of sertraline in inhibiting the serotonin (5-HT) transporter, but the metabolite is equipotent with sertraline in its affinity for the hepatic isoenzyme CYP2D6 (Fuller et al. 1995). The major metabolite of risperidone, 9-hydroxyrisperidone, has pharmacological effects similar to its precursor as a dopamine type 2 (D_2) and serotonin type 2 ($5\text{-}HT_2$) antagonist but differs in its affinity for and inhibition of the drug transporter P-gp (Zhu et al. 2007).

When switching therapy from one drug or drug class to another, the presence of any active metabolites should be considered (Garattini 1985). Norfluoxetine, for example, has an average half-life of 8–9 days, much longer than the average of 2–3 days for fluoxetine, its parent drug (DeVane 1994), and is an equipotent serotonin reuptake inhibitor. It may take several weeks for this metabolite to clear the body after discontinuation of fluoxetine (Pato et al. 1991). A similar situation applies to aripiprazole and its active metabolite, dehydro-aripiprazole, which have elimination half-lives of 75 hours and 94 hours, respectively.

Metabolites will accumulate to a steady state in the body in relation to their elimination half-lives and not those of their parent drugs. For a drug that is nearly completely metabolized in the liver, a characteristic of numerous psychoactive drugs, the produced metabolites will always have an elimination half-life that is equal to or longer than the half-life of the parent drug. This is a logical conclusion of considering that a metabolite cannot be eliminated faster than it is formed. Of course, administration of the metabolite as a separate molecular entity apart from the parent drug would produce a drug concentration–time curve independent of any influence of the metabolite being formed from a precursor in vivo. For some drugs, the full expression of direct pharmacological effects may not be expected until both the drug and any important active metabolites have all attained their steady-state concentration. For drugs producing indirect effects when the response depends on second messengers or a cascade of receptor actions, the waiting period for fully expressed effects may be even longer.

Stereochemistry

Stereochemistry or chirality of drug molecules is an increasingly important consideration in pharmacokinetics. Many psychoactive drugs exist as two or more stereoisomers or enantiomers with distinctly different biological properties and are marketed as the racemic (i.e., 50:50) mixtures of both isomers. Although enantiomers have identical physicochemical properties, they are often recognized as distinct entities by biological systems and may bind to transport proteins, drug-metabolizing enzymes, and pharmacological effect sites with different affinities. As a result, one enantiomer may possess a significant pharmacological effect, while the other stereoisomer may lack similar effects or produce different effects. Enantiomers may also differ in their absorption, metabolism, protein binding, and excretion, leading to substantial differences in pharmacokinetic properties (DeVane and Boulton 2002). Furthermore, one isomer may modify the effects of the other.

The development of single-isomer drugs may offer advantages over use of the racemic mixture. Potential advantages include a less complex and more selective pharmacological profile, a potential for an improved therapeutic index, a more simplified pharmacokinetic profile, a reduced potential for complex drug interactions, and a more definable relationship between plasma drug concentration and effect. Examples of racemic mixtures in current use include methadone, methylphenidate, bupropion, venlafaxine, fluoxetine, and citalopram. Clearly, each drug needs to be considered individually with regard to its development as a single stereoisomer formulation. Recent examples of successful switches to single isomers are escitalopram and dexmethylphenidate.

Pharmacogenetics

Inheritance accounts for a large part of the variations observed in the ability to eliminate drugs (see Figure 8–1) among individuals. This forms the basis of *pharmacogenetics,* which is defined as the study of the genetic contribution to the variability in drug response (Kalow et al. 1986; Price Evans 1993). This term was originally applied to the effect on pharmacokinetics, while pharmacogenomics dealt specifically with genes mediating drug response. More recently, the terms have been used interchangeably. Numerous association studies have been performed of genetic polymorphisms of molecular targets as predictors of disease susceptibility, specific drug response, and tolerability. This topic is covered in the chapter addressing pharmacogenomics (see Chapter 3, "Genetics and Genomics"). The genetic differences in pharmacokinetics that have been detected apply mostly to drug metabolism. The renal clearance of drugs appears to be similar in age- and weight-matched healthy subjects with no defined genetic polymorphisms. Genetic polymorphisms have been identified and defined for some drug transporters, primarily P-gp, and several hepatic enzymes important for the cellular transport and metabolism of many drugs used in psychopharmacology. These genetic polymorphisms are summarized in Table 8–2.

P-gp, as the most thoroughly studied drug transporter, appears to be significantly involved in the disposition of a variety of psychoactive drugs (Mahar Doan et al. 2002) (see Table 8–2). More than 70 polymorphisms have been reported in the *ABCB1* gene that encodes for P-gp, and three single-nucleotide polymorphisms (SNPs) of P-gp have been associated with functional changes in P-gp activity. The majority of SNP-related reports focus on the silent C3435T SNP of exon 26. It has been associated with changes in expression resulting in increased serum concentrations of digoxin and fexofenadine (Hoffmeyer et al. 2000; Kurata et al. 2002). There is emerging evidence that haplotypes of P-gp SNPs may influence drug-resistant epilepsy (Siddiqui et al. 2003), access of drugs to the

brain (Brunner et al. 2005), and placental transfer of psychoactive drugs (Rahi et al. 2007). Theoretically, P-gp substrates may act as competitive inhibitors of P-gp, so that drug–drug interactions may also involve P-gp (Wang et al. 2006).

Genetic polymorphism in a drug-metabolizing enzyme can result in subpopulations of people who may deviate substantially from the population mean in their ability to metabolize substrates of the affected enzyme. People who are poor metabolizers constitute at least 1% of the population, but the majority of people are normal or rapid metabolizers, and some are identified as ultrarapid metabolizers due to duplicate or multiple genes. The genetic polymorphisms in listed Table 8–2 were identified mostly as a result of adverse drug reactions to typical drug doses. Subsequent studies have used debrisoquine, sparteine, and dextromethorphan as probe drugs to calculate a metabolic ratio (MR) as an index of the relative ability of an individual to metabolize CYP2D6 substrates, thereby providing a phenotype identity. The MR is equal to the concentration of parent drug divided by the concentration of the major metabolite determined in the urine excreted during a timed interval following an oral dose. Similar methodology has been applied to study the metabolism of prototype substrates for a variety of hepatic enzymes (Price Evans 1993).

The results of many pharmacogenetic studies appear similar to the frequency distribution histograms in Figure 8–10. The frequency in Figure 8–10A is expected when enzyme activity is distributed normally within a population without genetic polymorphisms. The range of values for the MR may be broad, which reflects a large variability in oxidation reaction capacity in the study population. Thus, vastly different dosages are required for many patients. The bimodal distribution in Figure 8–10B is a typical finding for an enzyme that has a genetic polymorphism. Values above the antimode for the reference (or "probe") drug define poor metabolizers, who are clearly differentiated from normal or extensive metabolizers. The probe drug need not be metabolized by only one enzyme, which characterizes the use of caffeine for phenotyping the enzyme activity of *N*-acetyltransferase and CYP1A2, but the overlap of other enzymes should be minimal to produce the specific metabolite of interest (Denaro et al. 1996). Comparison of MRs between many patients of different ethnic origins has yielded measures of variability in enzyme activity in the population (Lin et al. 1996). The widespread availability of a commercial microarray chip for genotyping limited CYP enzymes has eliminated the need to perform phenotyping procedures in most circumstances. While a genotypical extensive metabolizer may be phenotypically a poor metabolizer, the opposite situation does not occur.

FIGURE 8–10. Theoretical frequency histograms of the distribution of the metabolic ratio of a model substrate showing a unimodal distribution among a population of normal or extensive metabolizers (A) and a bimodal distribution among a population including poor metabolizers and ultrarapid metabolizers (B).

The potential clinical consequences of being a poor metabolizer will vary according to the activity of the administered drug and any active metabolites. When the drug is active and a pathway is affected (a situation that usually produces an inactive metabolite), higher drug concentrations can be expected. This result can lead to an exaggerated response and potential toxicity. The most serious consequences would be expected from drugs with a narrow therapeutic window (see Table 8–1). For example, when perphenazine (a drug with a narrow therapeutic window) was given to elderly patients who were poor metabolizers of CYP2D6, extrapyramidal side effects were exaggerated (Pollock et al. 1995). If the therapeutic effects depend on the formation of an active metabolite, diminished response can be expected from a lower concentration of metabolite in poor metabolizers. For example, normal doses of codeine, which is partially metabolized to the more potent morphine, may provide an inadequate analgesic effect.

For CYP2D6, the poor-metabolizer status is inherited as an autosomal recessive trait. At least 70 different alleles have been defined for the *CYP2D6* gene, and many types of null mutations result in impaired CYP2D6 activity (Gonzalez and Idle 1994). Methods based on polymerase chain reaction (PCR) have a high sensitivity for detecting the mutant alleles and can establish a genotype. This procedure can be beneficial in drug development to test compounds that are CYP2D6 substrates and in some forensic circumstances to help establish the cause of excessive drug concentrations. Genetic phenotyping is potentially more clinically useful than genotyping and can be done when patients are drug free to characterize their relative ability to metabolize CYP2D6 substrates. About 1% of Caucasians are ultrarapid metabolizers because of an amplification of the functional *CYP2D6* gene (Johansson et al. 1993). These patients have the lowest MR when phenotyped with a CYP2D6 substrate with a high urinary concentration of metabolite and a low parent drug concentration (see Figure 8–10B). The implication is that these individuals will often require very high drug doses. Research is needed to support phenotyping and genotyping as an aid in the initial selection of drugs and drug doses for individualizing medicine.

Of the human cytochrome P450 enzymes, three families (CYP1, CYP2, and CYP3) are involved in drug metabolism (Guengerich 1992; Wrighton and Stevens 1992). The enzymes most relevant to psychopharmacology were listed in Table 8–1. Interindividual differences in the expression and catalytic activities of cytochrome P450 result in a large variation in the in vivo metabolism of drugs. The average immunoquantified levels of the various specific P450

enzymes in 60 human liver microsomal samples were reported by Shimada et al. (1994). Benet et al. (1996) and Wrighton and Stevens (1992) estimated the participation of the liver cytochrome P450 enzymes in drug metabolism based on known substrates and pathways (see Table 8–1). These values are compared in Table 8–3. CYP3A has the highest level of P450 in the liver and participates in the metabolism of the largest number of drugs. Together, CYP3A and CYP2D6 participate in the metabolism of an estimated 80% of currently used drugs.

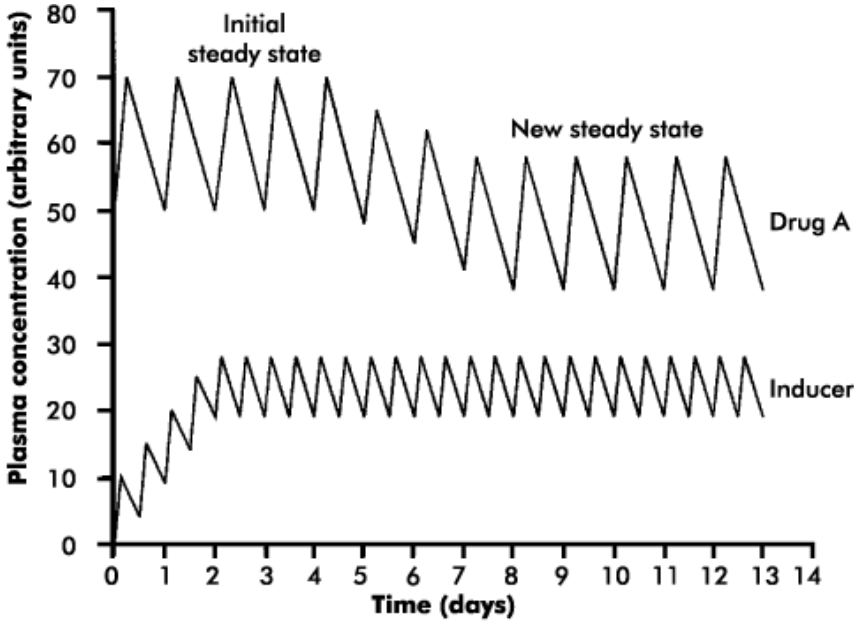
In 2004, the U.S. Food and Drug Administration approved the AmpliChip CYP450 Test (Roche Diagnostics Corporation, Indianapolis, IN) as a regulated pharmacogenetic test. This device uses a DNA microarray platform to assess the presence of the polymorphic form of the *CYP2D6* and *CYP2C19* genes. As these enzymes metabolize a substantial number of psychoactive drugs, use of this device should facilitate individualized medicine in psychiatry. Unfortunately, research demonstrating a clinical benefit from use of this technology is lacking.

In summary, recent pharmacogenetic investigations have yielded fruitful data relating to the causes of pharmacokinetic variability in the dose–effect relationship. The polymorphism of molecular drug targets in the brain is a source of pharmacodynamic variability. This topic is covered in the chapter addressing pharmacogenomics (see Chapter 3, "Genetics and Genomics"). Pharmacogenetic studies have extensively used metabolic phenotyping with model substrates for specific enzymes to characterize several genetic polymorphisms (see Table 8–2). The practical implications of metabolic phenotyping are most meaningful when the metabolic pathways of therapeutically administered drugs are known and when drug concentration has been correlated to either therapeutic or toxic effects (Gonzalez and Idle 1994). In this situation, knowledge of enzyme activity will serve as a guide to initial dosing and also allow a prediction of the significance of potential drug–drug interactions.

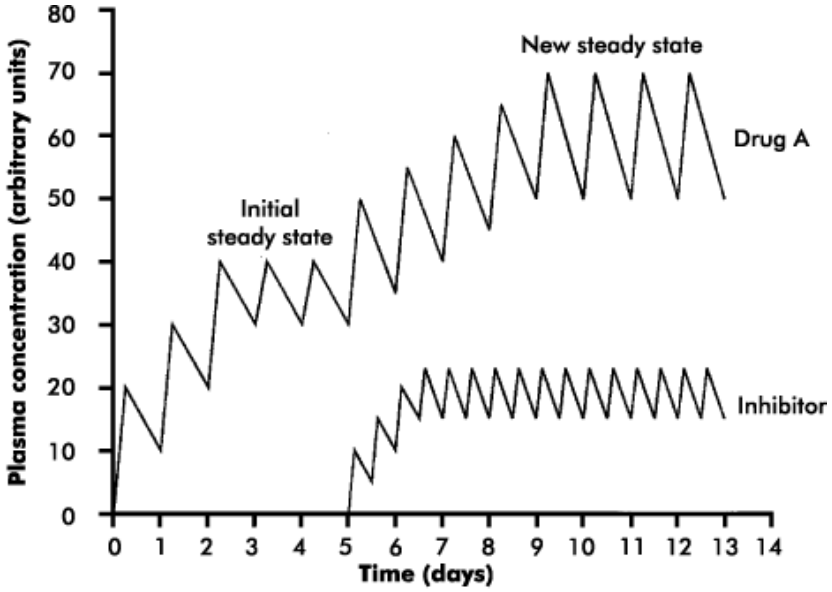
Drug Interactions



Drugs are frequently coadministered to achieve therapeutic effects from the combined actions at effect sites or to treat the adverse effects caused by one drug with another. Drug combinations routinely used include hypnotics with antidepressants, anticholinergic–antiparkinsonian drugs with antipsychotics, benzodiazepines with SSRIs, and mood stabilizers with antipsychotics. The use of more than one antidepressant or antipsychotic in combination for specific patients is increasingly encountered in clinical practice (Papakostas et al. 2007). When more than one drug is administered concurrently to a patient, the drugs may interact either in a positive manner or in a negative or undesired way because of either pharmacodynamic or pharmacokinetic mechanisms.

Pharmacodynamic interactions are likely to occur when the combination of an MAO inhibitor and an SSRI produces a serotonin syndrome and when the combination of ethanol and a benzodiazepine leads to psychomotor impairment. Two drugs may have affinity for the same receptor sites in the brain and produce additive or synergistic effects, or their actions may oppose each other through antagonistic interactions at receptor sites. Most often, pharmacodynamic mechanisms are not such obvious causes of drug interactions and are usually less easily determined and investigated than pharmacokinetic interactions.

The kinetics of drug interactions has been extensively described and is a routine focus of clinical investigations as



part of drug development (Brosen 1996; Rowland and Matin 1973). Two major mechanisms of drug interactions involve an alteration of metabolism through either induction or inhibition of hepatic cytochrome P450 enzymes. Major differences exist in the pharmacokinetic consequences of these interactions. The expected changes are illustrated in Figures 8–11 and 8–12. In Figure 8–11, the steady-state plasma concentration of drug *A* following continuous intermittent dosing is altered by the addition of an enzyme inducer. After the inducer is started, the effects on the steady-state concentration of drug *A* do not occur for several days while additional enzyme that metabolizes drug A is synthesized. Ultimately, an increase in the metabolic clearance of drug *A* accompanied by a decrease in its steady-state plasma concentration occurs. The degree to which clearance is increased will depend on the relative importance of the particular induced enzymes in the overall elimination of drug *A* and the dose and potency of the inducer. A clinically significant example of this type of interaction is the loss of oral contraceptive effect by carbamazepine induction of CYP3A4. The time required for a new steady state of drug *A* to occur following enzyme induction and the extent to which plasma concentrations decrease will depend on how marked a change in clearance occurs and the resulting change in drug half-life.

In contrast to the delayed effects of an inducer on drug *A*, the addition of an inhibitor causes an immediate increase in the plasma concentration of drug *A* (see Figure 8–12). This increase occurs as a result of a competitive inhibition of the relevant hepatic enzyme. Drug *A*'s plasma concentration rises to a new steady state consistent with a change in its clearance. The time required to achieve the new steady state is greater than the time to achieve the initial steady state, because the half-life is now prolonged relative to its original value. The full effect of an inhibitory interaction may not be realized until the inhibitor also reaches a steady state, because the degree of inhibition will also depend on the concentration of the inhibitor (Houston 1994; von Moltke et al. 1994, 1995).

Drug interactions are graded phenomena. The degree of interaction depends on the concentration of interacting drugs and, therefore, on the dose and timing of administration. Drug interactions are most likely to be detected when therapy with an interacting drug is initiated or discontinued. The clinical significance will depend on the particular drugs involved, the physiological state of the patient, the presence of concurrent illness, and other factors. Drugs with a narrow concentration range over which therapeutic effects are present without incurring toxicity are more likely to be involved in clinically significant drug interactions. These drugs include theophylline, some antiepileptic drugs, and antiarrhythmics (see Table 8–1).

When selecting a specific drug from a class of drugs to treat mental illness, its efficacy, safety, cost, and history of response are pertinent considerations. The introduction of the SSRIs has emphasized the critical importance of also considering potential drug interactions (Brosen 1996). Some of these antidepressants have been shown in vitro and in vivo to be potent inhibitors of specific cytochrome P450 isoenzymes (Crewe et al. 1992; Nemeroff et al. 1996; von Moltke et al. 1994, 1995). The most thoroughly studied reaction is the competitive inhibition of CYP2D6. Pharmacokinetic studies in healthy volunteers have provided a rank order of the potency for increasing the plasma concentration of model substrates. Case reports in patients have confirmed the existence of some interactions, and many others remain theoretical possibilities. Table 8–4 provides an overall ranking of the cytochrome P450 inhibitory potential of the antidepressants based on both in vitro and in vivo data. The rational selection of an antidepressant should include consideration of its potential enzyme inhibition when therapy is to be combined with substrates listed in Table 8–1, which may be inhibited by the specific antidepressant. Reviews (Harvey and Preskorn 1996; Nemeroff et al. 1996) describe the specific in vivo reports in more detail. While numerous interactions are possible, their clinical significance is a topic that continues to be debated (DeVane 2006; Preskorn and Werder 2006). Compensatory mechanisms and patterns of practice that minimize the expression of significant interactions include parallel pathways of drug elimination, dose dependence of inhibition and induction, initiating dosage at lower starting doses, and careful attention to patient response (DeVane 2006). Although some interactions have an unequivocal high likelihood for adverse events (e.g., drug combinations that can result in a serotonin syndrome), severe adverse interactions appear to be rare events.

The selection of a drug based on its cytochrome P450 inhibitory potential should not be limited to the newer antidepressants (see Table 8–4). Combining any two drugs that are substrates for the same enzyme increases the likelihood of competitive enzyme inhibition. All of the substrates listed in Table 8–1 are potential inhibitors. For example, nortriptyline, desipramine, and thioridazine are potent inhibitors of CYP2D6. In vitro methods using microsomal incubations to predict in vivo interactions have appeared and are based on accepted pharmacokinetic principles (Gillette 1971; Houston 1994; von Moltke et al. 1994, 1995). These screening techniques are now used extensively in the pharmaceutical industry in drug development. The knowledge of isoenzyme-specific metabolism of new and established drugs is expanding rapidly and holds promise for further enabling the selection of combined pharmacotherapy based on pharmacokinetic principles.

The increasingly recognized role of drug transporters in the disposition of psychoactive drugs has led to the proposition that inhibition or induction of transporter activity may be involved as a mechanism of drug interactions. Risperidone and its metabolite paliperidone, along with some antidepressants, have been shown in vitro to be inhibitors of P-gp (Doran et al. 2005; Zhu et al. 2007). Reports of clinically significant interactions related to these effects have yet to emerge.

CONCLUSION

The use of drugs in psychopharmacology can be problematic as a result of pharmacokinetic and pharmacodynamic variability in the dose–effect relationship. Some sources of variability can be controlled through application of pharmacokinetic principles in dosage regimen design and therapeutic drug monitoring. Understanding of pharmacodynamic principles contributes to individualization of dosage regimens. The database on the genetic contribution to drug response and the interactions between drugs is rapidly expanding. Future application of this knowledge will further enhance pharmacotherapy for mentally ill patients.

Chapter 9. Brain–Immune System Interactions: Relevance to the Pathophysiology and Treatment of Neuropsychiatric Disorders

BRAIN–IMMUNE SYSTEM INTERACTIONS: RELEVANCE TO THE PATHOPHYSIOLOGY AND TREATMENT OF NEUROPSYCHIATRIC DISORDERS: INTRODUCTION

Although once considered heresy, the notion that meaningful interactions occur between the brain and the immune system has become scientific dogma. This change in scientific orthodoxy results from more than 30 years of research demonstrating that brain-mediated events, such as psychological stress and depression, can alter peripheral immune system functioning and, conversely, that changes in peripheral immune functioning, such as those that occur during illness, can profoundly affect the brain, leading to clinically meaningful changes in mood, anxiety, and cognition. In this chapter, we provide an overview of brain–immune system interactions that are of potential relevance to the field of psychiatry.

This effort needs to be understood within the far wider context of psychoneuroimmunology, which is the interdisciplinary field that focuses on brain–mind–immune system interactions. When Robert Ader first coined the term *psychoneuroimmunology* as a title for his textbook on brain–immune system interactions in 1981, the resulting text filled a single slim volume (Ader 1981). In contrast, the most recent edition fills two volumes, each running more than 1,000 pages, and covers topics as diverse as gene–ribonucleic acid interactions within the cellular nucleus and the effects of spirituality on the immune system (Ader 2007).

THE IMMUNE SYSTEM: AN OVERVIEW

When considered in the broadest sense as the process whereby organisms maintain functional and organizational integrity against foreign encroachment, immunity is clearly a prerequisite to life itself. Given this, it is not surprising that even the simplest of organisms demonstrate immune functioning, which is consistent with the notion that immunity arose early in the evolution of life on earth (Maier and Watkins 1998). In vertebrates, the immune system has evolved a wide array of separate, but cooperative, mechanisms that serve to attack invading pathogens, destroy tumor cells, and remove and repair damaged tissue. From an evolutionary perspective, the high rate of autoimmune disorders, such as multiple sclerosis and rheumatoid arthritis, suggests that the adaptive advantages of robust immune system functioning outweigh the frequently disastrous consequences engendered when the immune system overreacts and begins attacking the self (Nesse and Williams 1994). The immune system review that follows is necessarily simplified. More extensive discussions of the immune system can be found elsewhere (Abbas and Lichtman 2004; Rabin 1999; Roitt et al. 1998).

Innate Versus Acquired Immunity

A primary distinction within the immune system is between innate immunity (also known as natural or nonspecific immunity) and acquired (or specific) immunity. Innate immunity provides a first line of defense by attacking foreign substances rapidly in a nonspecific manner, without requiring that a specific antigen (or antibody-generating molecule) be recognized (Table 9–1). Although this lack of antigenic specificity precludes the development of an immunological memory to speed the response

should a pathogen be encountered again in the future, the nonselectivity of the innate immune system allows for a rapid response to a wide variety of environmental assaults. The immediate response sets in motion a complicated series of processes that contribute to activation of the acquired immune system, which responds more slowly, but far more selectively, to the particular invading entity. An acquired immune response requires specific recognition of a foreign substance and allows for the establishment of memory cells that react far more quickly when the same substance is again encountered. Finally, both innate and acquired immune systems contain mechanisms to control and extinguish activation; therefore, immune activity, with its attendant metabolic costs and danger of self attack, does not become self-perpetuating.

TABLE 9–1. Major divisions of the immune response

	Acquired immune response		
	Innate immune response	**Cellular response**	**Humoral response**
Effector cells	Phagocytes (macrophages, neutrophils), NK cells	Th1 lymphocytes, cytolytic T lymphocytes	Th2 lymphocytes, B lymphocytes
Soluble mediators	Complement, acute-phase reactants		Antibodies
Representative cytokines	TNF-α, IL-1α and β, IL-6	IL-2, IL-12, IFN-γ	IL-4, IL-10

Note. IFN = interferon; IL = interleukin; NK = natural killer; Th1 = T-helper 1; Th2 = T-helper 2; TNF = tumor necrosis factor.

Innate immunity begins with the skin and other mucosal surfaces lining the gastrointestinal and respiratory tracts, which provide a physiochemical barrier to invasion by foreign pathogens. When these surfaces are breached, phagocytic cells, such as macrophages, microglia (in the brain), and certain dendritic cells, recognize invading pathogens through relatively crude pattern-recognition molecules referred to as toll-like receptors and, depending on the cell type, ultimately engulf and destroy these foreign agents. Upon activation, these cells and other participants in the early innate immune response (e.g., natural killer [NK] cells) release soluble, proteinaceous, immune mediators known as cytokines. Cytokines that mediate innate immunity include the type I interferons, which have direct antiviral effects, and proinflammatory cytokines. Of these, interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor–α (TNF-α) are important in inducing inflammation at the site of pathogen invasion or tissue damage. IL-6 also plays a central role in stimulating the liver to produce a host of acute-phase reactants, such as C-reactive protein; α_1-acid glycoprotein; complement C3; haptoglobin; α_2-macroglobulin; α_1-antitrypsin; ceruloplasmin; and α-, β-, and γ-fibrinogen (Baumann and Gauldie 1994). These proteins, which make up the acute-phase response, serve to both facilitate destruction of foreign substances and limit tissue damage from immune activation. In addition to the release of cytokines and acute-phase proteins, other molecules are induced, including chemokines and adhesion molecules, which assist in the recruitment of multiple cell types to the site of infection and/or tissue damage and destruction. Depending on the magnitude of the innate immune response, relevant cytokines can enter the peripheral blood or activate local afferent nerve fibers and have potent effects on the neuroendocrine system, especially the hypothalamic-pituitary-adrenal (HPA) axis and the central nervous system (CNS), where they mediate many symptoms of illness, including fever, loss of appetite, social withdrawal, and sleep changes (Maier et al. 1998). These behavioral changes are believed to subserve the metabolic demands inherent in the task of fighting infection and maintaining an elevated body temperature.

Acquired immunity relies on hematopoietically derived lymphocytes, which have the ability to specifically recognize an astoundingly wide array of foreign substances. These lymphocytes fall into

two general categories. T lymphocytes mature in the thymus and mediate cellular immunity, which is essential for protection against intracellular pathogens, such as viruses and mycobacteria. B lymphocytes mature in the bone marrow and produce antibodies that are especially effective in neutralizing bloodborne and extracellular pathogens, such as parasites, viruses in replication phase, and many species of bacteria. A further key function of the acquired immune system is to screen out lymphocytes that might react against self molecules. When this essential function fails, autoimmune conditions can result.

Like innate immunity, acquired immunity utilizes soluble cytokine mediators. It is generally recognized that an acquired immune response develops along one of two lines, Th1 or Th2, on the basis of the cytokine profiles induced by T-helper CD4 cells (Elenkov and Chrousos 1999). A Th1 response is characterized by cytokines that promote cell-mediated inflammatory reactions, such as delayed-type hypersensitivity (DTH). These cytokines include interleukin-2 (IL-2), interleukin-12 (IL-12), tumor necrosis factor–β (TNF-β), and interferon-γ (IFN-γ). Cytokines generated by T-helper cells during a Th2 immune response include interleukin-4 (IL-4), interleukin-9 (IL-9), and interleukin-10 (IL-10). IL-6 is also produced by CD4 cells during a Th2-type acquired immune response. The development of a Th2 response favors antibody production, may provide protection against parasites, and is associated with allergic and hypersensitivity reactions.

An acquired immune system response consists of three phases: an induction phase, in which the system detects the presence of antigen; an activation phase, in which the presence of antigen triggers the expansion of antigen-specific T and B cells; and an effector phase, in which the foreign substance is cleared from the body (Miller et al. 2000). In this process, the acquired immune system utilizes and empowers many innate immune elements. For example, the coating of bacteria by B cell–produced antibodies enhances the ability of innate immune system phagocytes to destroy pathogens. Like other complicated physiological response systems, the immune response has built-in negative feedback elements that have evolved to limit immune reactivity once the pathogenic challenge has been met. Other bodily systems, including the HPA axis, perform important extrinsic immunomodulatory roles, and when functioning optimally, these systems limit inflammation and immune system proliferation. A final feature of the acquired immune system, which is central to its functioning, is the formation of long-lived B and T lymphocytes that serve as memory cells for recognizing an antigen should it be encountered in the future. This mechanism accounts for the ability of acquired immunity to mount far more rapid and effective responses to previously seen antigens. It also provides the physiological basis for the effectiveness of vaccines, which activate acquired immunity toward a specific pathogen without inducing illness.

BRAIN TO BODY: CENTRAL NERVOUS SYSTEM EFFECTS ON THE IMMUNE SYSTEM

Despite the fact that a general belief in the ability of psychological states to affect health has been apparent since antiquity, scientific formulations, until recently, have tended to view the CNS and the immune system as separate and noninteracting entities. Indeed, the immune system has historically been conceptualized as autonomous and self-contained, with a purpose that begins and ends with the tasks of protection against infection and malignancy and the repair of damaged tissue. Such a view tends to preclude any physiological mechanism by which mental events might directly affect immune functioning. However, in the 1970s, researchers made the startling discovery that the immune system was amenable to classical Pavlovian conditioning (Ader and Cohen 1975). Numerous studies have confirmed and extended this initial insight and established beyond argument the ability of brain states to significantly modulate immune system functioning. The majority of these studies have focused on the effects of stress on the immune response. Virtually every type of stressor, ranging from laboratory stressors (e.g., public speaking, mental arithmetic) to more naturalistic stressors (e.g., bereavement, loneliness, and academic examinations), has demonstrated a measurable effect on the immune response, including effects on various aspects of both innate and acquired immunity (Raison et al.

2002). Although the relationship between stress and immunity is quite complex, more acute and/or mild stressors, in general, tend to be associated with activation of immune responses, whereas more chronic and intense stressors tend to be associated with activated innate immune system elements and impaired acquired immune system responses. The health relevance of these stress-related immune changes has been demonstrated in studies that have shown an association between chronic stress and increased susceptibility to the common cold, reduced antibody responses to vaccination, and delayed wound healing (Cohen et al. 1991; Glaser et al. 1992; Kiecolt-Glaser et al. 1995). In addition, stress, as well as depression, has been linked to increased morbidity and mortality in infectious diseases (e.g., HIV infection), neoplastic diseases (including breast cancer and malignant melanoma), diabetes, and cardiovascular disease (Evans et al. 2005; Fenton and Stover 2006; Leserman et al. 1999; Raison and Miller 2003a).

Effects of Depression and Stress on Acquired Immune (Lymphocyte) Responses

In psychiatry, the practical import of connections between brain outflow pathways and the immune system has been best documented in the effects of stress-related disorders, especially major depression, on immune functioning. Despite a significant degree of heterogeneity across individual studies, significant evidence suggests that patients with major depression demonstrate a number of immune changes similar to those seen in individuals undergoing chronic and/or severe stress (Herbert and Cohen 1993; Zorrilla et al. 2001). This is hardly surprising, given the many indices of stress system hyperactivity that are apparent in patients with major depression, including increased corticotropin-releasing hormone (CRH) and cortisol production (Pariante et al. 1995) and augmented sympathetic nervous system (SNS) activity as manifested in part by increased peripheral blood catecholamines (Veith et al. 1994; Wong et al. 2000). Enumerative immune changes shared by major depression and chronic/severe stress include a decrease in lymphocytes, B cells, and T cells and an increase in the ratio of CD4 to CD8 T cell subsets (Herbert and Cohen 1993). Shared functional changes include a decrease in NK cell activity and lymphocyte proliferation in response to nonspecific mitogens (Herbert and Cohen 1993; Zorrilla et al. 2001).

In a meta-analysis examining the issue, major depression was found to have a larger effect than stress on these immune variables (Zorrilla et al. 2001) (Table 9–2). It is important to note, however, that major depression is a heterogeneous condition and that immune changes are not uniform across all patients. Indeed, inhibited lymphocyte responses tend to be most striking in patients who are older, are hospitalized, or have more severe and/or melancholic types of depression (Miller 1998; Schleifer et al. 1989). In addition, the sleep changes common in depression are known to alter lymphocyte responses, especially NK cell activity (NKCA), even in the absence of other depressive symptoms (Irwin et al. 1996). Nonetheless, it does not appear that these factors completely account for the association between major depression and alterations in measures of the number and function of lymphocyte subsets (Herbert and Cohen 1993).

TABLE 9–2. Immune alterations in major depression

Increased white blood cells
Increased neutrophil percentage
Decreased lymphocyte percentage
Increased CD4-to-CD8 ratio

Compared with chronic/severe stress, major depression has been less well characterized in terms of effects on in vivo functional immunity; however, the little evidence that is available suggests that depression, like chronic/severe stress, may impair T-cell function in ways that are relevant to disease vulnerability. For example, although it is not known whether major depression is associated with an increase in antibody titers to latent viruses, one study reports that patients with major depression have a marked decrease in the ability to generate lymphocytes that respond to the herpes zoster virus (Irwin et al. 1998). Also consistent with impaired T-cell function in depression is the observation that depressed patients, especially those with melancholia, demonstrate impaired DTH (Hickie et al. 1993).

Effects of Depression and Stress on Innate Immune Inflammatory Responses

Although stress and depression have been most often seen as suppressing lymphocyte function, emerging data suggest that such a conclusion oversimplifies the complexities of the mammalian immune response to environmental perturbation and that stress indeed may also activate certain aspects of the immune system (Raison and Miller 2001; Raison et al. 2006). For example, stress exposure in animals and humans has been shown to increase the expression of innate immune cytokines (Goebel et al. 2000; Maier and Watkins 1998; Paik et al. 2000), activate microglia (Frank et al. 2007), and sensitize subsequent immune responses to inflammatory immune challenge (Johnson et al. 2004). Peripheral production of either IL 1β or its soluble receptor antagonist (sIL-1ra), as well as IL-6, has been reported to be increased in the context of several acutely stressful situations, including exercise, academic examinations, and laboratory stressors (Ackerman et al.1998; Goebel et al. 2000; Maes et al. 1998; Pace et al. 2006; Paik et al. 2000; Steptoe et al. 2001). While the mechanism by which stress induces cytokine production has yet to be fully elucidated, it has been shown that catecholamines may play an important role. In particular, β- but not α-adrenoreceptors are critical for central production of inflammatory cytokines, whereas both α- and β-adrenoreceptors contribute to the induction of plasma cytokines following stress (Johnson et al. 2005). These effects of stress appear to be mediated in part by activation of inflammatory signaling pathways including nuclear factor kappa B (NF-κB), which is a linchpin in the initiation of the inflammatory response following the stimulation of toll-like receptors as well as relevant cytokine receptors (Bierhaus et al. 2003).

A growing database suggests that depression (in addition to stress) in both medically healthy and medically ill patients is associated with innate immune system activation (Andrei et al. 2007; Kim et al. 2007; Lesperance et al. 2004; Maes 1999; Musselman et al. 2001b; Raison et al. 2006). Findings consistent with inflammatory activation in depression include increased plasma and cerebrospinal fluid (CSF) concentrations of inflammatory cytokines, increased in vitro production of proinflammatory cytokines from stimulated peripheral blood mononuclear cells, increased acute-phase proteins (and decreased negative acute-phase proteins), increased chemokines and adhesion molecules, and increased production of prostaglandins (Kim et al. 2007; Maes 1999; Raison et al. 2006). Based on meta-analyses, increases in peripheral blood IL-6 and C-reactive protein are two of the most reliable inflammatory biomarkers associated with depression (Zorrilla et al. 2001). Indeed, careful studies examining IL-6 across the circadian cycle have shown a reverse circadian pattern of IL-6 in depressed patients, with markedly elevated levels of this cytokine compared with control subjects during the morning hours (Alesci et al. 2005). Interestingly, given the role of IL-6 and C-reactive protein in predicting disease outcome in both cardiovascular disorders and diabetes (Ridker et al. 2000a, 2000b), as well as data indicating that inflammation may play a role in cancer (Aggarwal et al. 2006), the relationship between depression and activation of the innate immune inflammatory response may provide a mechanism that explains the negative impact of depression on a number of illnesses (Evans et al. 2005). Moreover, immune activation in major depression may be involved in several of the

pathophysiological changes that are common in the context of depression, including bone loss, insulin resistance, cachexia, increased body temperature, and hippocampal volume loss (Raison et al. 2006). Interestingly, activation of innate immune responses following stress and depression may also contribute to stress- and depression-induced decreases in acquired immune (lymphocyte) responses. For example, administration of IL-1ra prior to stressor exposure has been found to reduce the inhibitory impact of stress on antibody production (Moraska et al. 2002).

There are a number of potential factors that may contribute to increased innate immune responses in depressed patients. One factor that has received special attention is body mass index (BMI). BMI has been reliably correlated with peripheral markers of inflammation including IL-6, in part related to the capacity of adipocytes to produce inflammatory cytokines (Schaffler et al. 2007). Relevant in this regard, an analysis of data from the Third National Health and Nutrition Examination Survey revealed that after adjustment for a multitude of variables, including BMI, there was a strong association between major depression and elevated levels of C-reactive protein in men but not women (Ford and Erlinger 2004). Early life stress is another factor that may be involved. For example, males with current major depression and increased early life stress exhibited significantly greater increases in IL-6 and NF-κB DNA binding following a psychosocial stressor compared with control subjects (Pace et al. 2006).

Given the anti-inflammatory properties of glucocorticoids (Rhen and Cidlowski 2005) (see below for further discussion of the immunological effects of glucocorticoids), it might be expected that patients with depression who have decreased glucocorticoid sensitivity, as manifested by nonsuppression of cortisol on the dexamethasone suppression test (DST), would be especially prone to showing evidence of immune activation. Some evidence suggests that this is indeed the case. Compared with patients with depression who have normal in vivo glucocorticoid sensitivity, patients who are DST nonsuppressors demonstrate increased plasma concentrations of the acute-phase reactant α_1-glycoprotein, as well as increased in vitro mitogen-stimulated IL-6 production (Sluzewska 1999). Glucocorticoid resistance, as assessed by the DST, has been associated with a poor response to antidepressant treatment (Holsboer 2000). Of interest, in light of the relationship between DST nonsuppression and increased inflammatory activity, findings suggest that patients with depression who are treatment resistant are more likely than patients who are treatment responders to show evidence of increased inflammatory activity, including increased plasma concentrations of acute-phase proteins, IL-6, and the soluble receptor for IL-6 (sIL-6r), which synergistically enhances IL-6 activity (Raison et al. 2006; Sluzewska 1999). Moreover, depressed patients who exhibit a decrease in unstimulated TNF-α during antidepressant treatment are more likely to respond than those whose TNF-α remains elevated (Lanquillon et al. 2000).

Other Psychiatric Disorders and the Immune Response

Some evidence suggests that other stress-related neuropsychiatric conditions may be associated with immune activation, although these conditions are less well characterized than major depression. These disorders include posttraumatic stress disorder (PTSD), chronic fatigue syndrome (CFS), seasonal affective disorder (SAD), and fibromyalgia. Patients with combat-related PTSD have been reported to demonstrate increased plasma concentrations of IL-1 and increased CSF concentrations of IL-6 (Baker et al. 2001; Spivak et al. 1997). PTSD following civilian disasters appears to be associated with elevated plasma concentrations of IL-6 and its soluble receptor (Maes et al. 1999c). Although not found consistently (Maes et al. 1999c), both severity of symptoms and duration of illness have been reported to correlate positively with indices of immune activation in PTSD (Miller et al. 2001; Spivak et al. 1997).

A growing body of literature suggests that patients exposed to early life trauma may be especially vulnerable to the development of psychophysical disorders (e.g., CFS, fibromyalgia) that are characterized by complaints of chronic pain, fatigue, and cognitive difficulties of unknown etiology

(Heim et al. 1997). Consistent with this, these disorders have also been associated with evidence of increased inflammatory activity. For example, it has been reported that both CFS and fibromyalgia are accompanied by an increase in acute-phase reactants and increased plasma concentrations and/or peripheral blood mononuclear cell production of proinflammatory cytokines, including IL-1, IL-6, and TNF-α (Borish et al. 1998; Cannon et al. 1999; Gupta et al. 1997; Maes et al. 1999b). Of note, one report indicates that SAD, a condition with significant symptom overlap with CFS and fibromyalgia, may be characterized by increased plasma concentrations of IL-6 (Leu et al. 2001).

Finally, although the picture is far less clear, there has been speculation that immune system activation may contribute to the pathophysiology of psychotic disorders, including schizophrenia, possibly related to an autoimmune diathesis (Pearce 2001; Rothermundt et al. 2001). Elevated levels of cytokines and their receptors, including IL-2, sIL-2, and IL-6, have been reported in the blood and CSF of patients with schizophrenia, and a high level of CSF IL-2 has been found to predict subsequent schizophrenic relapse (Rothermundt et al. 2001). In a related fashion, consideration has been given to the role of viral infection early in development (Pearce 2001), based on seasonal birth patterns that have been reliably replicated in large epidemiological studies of patients with schizophrenia. These findings are consistent with in utero infections of relevant brain structures, including the hippocampus, during critical periods of development (especially during the second trimester) (Pearce 2001). Moreover, cross-reactivity between brain antigens and antigens of infectious agents may contribute not only to schizophrenia but also to the neurological and psychiatric complications associated with streptococcal infection (i.e., pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections [PANDAS]) (Snider and Swedo 2000).

MEDIATING PATHWAYS

Underlying the ability of the CNS to affect the immune system is a host of connections between autonomic and neuroendocrine pathways and immune system elements. Immune cells are able to directly respond to brain outflow pathways via receptors for small-molecule neurotransmitters, adrenal and gonadal steroids, hypothalamic-releasing factors, and other neuropeptides (Raison et al. 2002). Specific receptor densities vary among immune cell types, and these variations correlate with cell sensitivity to a given ligand.

Autonomic Nervous System

It is well known that sympathetic and parasympathetic pathways within the autonomic nervous system (ANS) interact to maintain homeostasis in a variety of physiological states, including regulation of the immune response. In addition to expressing receptors for autonomic and neuroendocrine signaling molecules, immune cells and tissues are innervated by fibers derived from the ANS, together comprising a neural pathway which can reflexively regulate the immune response (Czura et al. 2007; Downing and Miyan 2000; Miller 1998; Raison et al. 2002; Sanders and Kavelaars 2007; Tracey 2002). For example, the sympathetic branch of the ANS sends fibers into immune tissues in association with the vascular supply. Within tissue parenchyma, these fibers are associated with vascular smooth muscle cells, where they regulate vascular tone. In addition, sympathetic nerve terminals have been observed by electron microscopy to exist in close approximation with lymphocytes and macrophages. Thus, the sympathetic branch of the ANS appears able to influence the immune system either by changing the vascular tone and blood flow into lymphoid organs or by directly influencing immune cell function via locally released neurotransmitters, especially norepinephrine and neuropeptides such as neuropeptide Y, substance P, vasoactive intestinal peptide, calcitonin gene–related peptide, and CRH, which, in turn, interact with specific receptors on nearby immune cells (Bellinger et al. 1997; Czura et al. 2007).

Initial conceptualizations of the effect of the SNS on immune functioning tended to view the system as being primarily immunosuppressive. Catecholamines are well known to diminish NKCA and nonspecific

mitogen-stimulated lymphocyte proliferation and appear to be the primary mediators of rapid immune changes in humans in response to acute stress paradigms (Raison and Miller 2001). Many of the immunosuppressive effects of catecholamines result from β-adrenergic receptor activation: blocking the β receptor obviates many of the stress-related immune alterations, especially those that occur in solid immune tissues, such as the spleen (Benschop et al. 1994; Cunnick et al. 1990; Rabin 1999; Sanders et al. 2007).

However, in recent years, it has become evident that the immune system effects of both norepinephrine and epinephrine cannot be adequately subsumed under a single rubric of immunosuppression. Indeed, as noted above, it has become apparent that catecholamines also have immune-activating effects, given data that catecholamines can stimulate the production of proinflammatory cytokines, especially IL-6, both in the periphery and in the CNS and activate inflammatory signaling cascades (Bierhaus et al. 2003; Johnson et al. 2005; Norris and Benveniste 1993; Papanicolaou et al. 1998). The ability of catecholamines to induce inflammation may be related in part to a "switch" that occurs whereby protein kinase A activation leads to β-adrenergic receptor phosphorylation, which in turn switches β-receptor signaling from G_s to G_i. G_i has been associated with activation of the ras inflammatory signaling cascade (Daaka et al. 1997). Of note, catecholamines also appear to favor the development of Th1 cellular immune responses and promote the production of the Th1 cytokine IFN-γ (Kohm and Sanders 2000). Consistent with this, β-adrenergic receptors are found on Th1 CD4 T cells, but not on Th2 cells (Kohm and Sanders 2000).

In addition to immune regulation by the sympathetic branch, the parasympathetic branch of the ANS has been shown to contribute to the regulation of innate immune responses via an efferent neural signaling pathway referred to as the *cholinergic anti-inflammatory pathway* (Tracey 2002). The existence of this pathway was initially identified in studies showing that stimulation of the vagus nerve attenuates immune system activation and the physiological signs of septic shock in response to lipopolysaccharide, a key component of gram-negative bacterial cell walls (Borovikova et al. 2000). Follow-up studies have determined that vagal release of acetylcholine, which in turn interacts with the α7 subunit of the nicotinic AChR (α7 nAChR) on relevant immune cells, is capable of suppressing production of cytokines, including TNF-α, via inhibitory effects on nuclear translocation of NF-κB (Altavilla et al. 2006; Guarini et al. 2003) and activation of Janus kinase (JAK) 2 signal transducers and activators of transcriptions (STAT) 3 (de Jonge et al. 2005; Pavlov and Tracey 2005). Subsequent studies have established that cytokine production is inhibited by efferent vagal pathways in the context of a variety of inflammatory processes, including myocardial ischemia, hemorrhagic shock, ischemia/reperfusion, and pancreatitis (Altavilla et al. 2006; Guarini et al. 2003; Mioni et al. 2005; van Westerloo et al. 2006; H. Wang et al. 2004). It also has been shown that both vagus nerve stimulation and α7nAChR agonists inhibit production of a number of proinflammatory cytokines, including TNF, IL-1, IL-6, IL-8, and high-mobility group box 1 (HMGB1) (H. Wang et al. 2004). Of note, a specific α nAChR-dependent vagus nerve pathway to the spleen has been identified that inhibits proinflammatory cytokine production during endotoxemia and polymicrobial sepsis. Furthermore, both splenectomy and vagotomy interrupt the cholinergic anti-inflammatory response (Huston et al. 2006). Taken together, these findings suggest that in addition to effects on cellular signaling, there are anatomical and hard-wired components of the cholinergic anti-inflammatory pathway.

Hypothalamic-Pituitary-Adrenal Axis

In concert with the ANS, the HPA axis serves as a central component of the mammalian stress response system. Although glucocorticoids, which represent the final product of HPA axis activation, have long been viewed as immunosuppressive because of their well-documented ability to suppress inflammation (largely through protein–protein interactions between the glucocorticoid receptor and NFκB) (Rhen et al. 2005), it is increasingly recognized that HPA axis effects on immunity are complex (Dhabhar et al. 1995). This complexity arises from the fact that HPA axis effects on the immune

system depend on numerous factors, including the immune compartment that is assessed, the element of the HPA axis being evaluated (i.e., CRH vs. cortisol), and the duration and timing relative to the immune response and stressor application. Thus, for example, glucocorticoids are known to acutely diminish CD4 cell counts in the blood; however, at the same time, glucocorticoids enhance CD4-mediated DTH reactions in the skin, through their effects on lymphocyte trafficking (Dhabhar 1998). Moreover, different HPA axis elements demonstrate divergent immune system effects. For example, the end result of CRH-induced HPA axis activation is proinflammatory cytokine suppression, and yet studies demonstrate that the direct effect of CRH on proinflammatory cytokine production may be stimulatory (Labeur et al. 1995; Paez Pereda et al. 1995).

Finally, the effect of glucocorticoids on naturalistic measures of immunity, such as DTH, depends on both the concentration and the duration of glucocorticoids within the immune compartment under consideration. Thus, low doses of glucocorticoids applied for brief periods have been shown in rodents to stimulate DTH, whereas higher (or more protracted) glucocorticoid exposure suppresses DTH (Dhabhar and McEwen 1999).

CRH applied within the CNS suppresses several measures of immunity, including splenic NKCA, mitogen-stimulated lymphocyte proliferation, and in vivo and in vitro antibody formation, as well as T-cell responses to T-cell receptor antibody (Caroleo et al. 1993; Irwin et al. 1988; Labeur et al. 1995; Rassnick et al. 1994). CRH-overproducing mice demonstrate a profound decrease in the number of B cells and severely diminished primary and memory antibody responses (Stenzel-Poore et al. 1994). These immunosuppressive effects appear to be mediated by stress response outflow pathways activated by CRH, given that blockade of the SNS abolishes CRH effects on NKCA and adrenalectomy obviates CRH effects on lymphocyte proliferation (Irwin et al. 1988; Labeur et al. 1995). In addition, the B-cell decreases in CRH-overproducing mice are consistent with the marked reduction in rodent B cells observed after chronic glucocorticoid exposure (Miller et al. 1994).

In contradistinction to its immunosuppressive properties, CRH has also been shown to enhance proinflammatory cytokine production in animals and humans when administered peripherally or within the CNS. Chronic intracerebroventricular administration of CRH to rats leads to induction of IL-1β messenger RNA (mRNA) in splenocytes, and acute intravenous administration in humans has been reported to cause a fourfold increase in the induction of IL-1α (Labeur et al. 1995; Schulte et al. 1994). Similarly, the addition of CRH to in vitro mononuclear cell preparations induces the release of IL-1 and IL-6 (Leu and Singh 1992; Paez Pereda et al. 1995). Both chronic and acute CRH infusion have also been reported to increase production of the immunoregulatory cytokine IL-2 in humans and animals (Labeur et al. 1995; Schulte et al. 1994). In addition to potential proinflammatory activities of CRH within the CNS, peripheral production of CRH has been demonstrated in inflammatory diseases, such as ulcerative colitis and arthritis, in which it appears to act as a local proinflammatory agent (Karalis et al. 1997; Nishioka et al. 1996).

Of all neurotransmitters or hormones known to modulate immune functioning, the actions of glucocorticoids, although complicated, are probably best understood (Raison et al. 2002). Identified effects of glucocorticoids on the immune (and inflammatory) system include

- Modulation of immune cell trafficking throughout the body (Dhabhar et al. 1995)
- Modulation of cell death pathways (i.e., apoptosis) (McEwen et al. 1997)
- Inhibition of arachidonic acid pathway products (e.g., prostaglandins) that mediate inflammation and sickness symptoms (e.g., fever) (Goldstein et al. 1992)
- Modulation of Th1/Th2 cellular immune response patterns in a manner that inhibits Th1 (cell-mediated) responses and promotes Th2 (antibody) responses (Elenkov and Chrousos 1999)
- Inhibition of T-cell– and NK-cell–mediated cytotoxicity (Raison et al. 2002)
- Inhibition of cytokine production and function through interaction of glucocorticoid receptors with transcription factors (NF-κB, in particular), which, in turn, regulate cytokine gene expression and/or the

expression of cytokine-inducible genes (McKay and Cidlowski 1999)

Although, as discussed below, glucocorticoids may actually enhance certain aspects of naturalistic immune functioning when produced for brief periods at low to moderate doses in the context of acute and/or mild stress, glucocorticoids, in general, play a primary role in restraining excessive or prolonged inflammatory activation (Munck 1989). This property has long been exploited by modern medicine for the treatment of autoimmune and other chronic inflammatory conditions, with the result that glucocorticoids remain a cornerstone of our anti-inflammatory armamentarium. Consistent with their pharmacological uses, glucocorticoids have been shown to be essential for inflammatory regulation in response to immune system activation. For example, neutralization of endogenous glucocorticoid function results in enhanced pathology and mortality in animals exposed to lipopolysaccharide, as well as other inflammatory stimulators, such as streptococcal cell wall antigen or myelin basic protein (Bertini et al. 1988; Sternberg et al. 1989). Similarly, rodents that have been rendered glucocorticoid deficient by adrenalectomy have markedly increased death rates following infection with murine cytomegalovirus, an effect that arises from unrestrained activity of the proinflammatory cytokine TNF-α (Ruzek et al. 1999).

BODY TO BRAIN: IMMUNE SYSTEM EFFECTS ON CENTRAL NERVOUS SYSTEM FUNCTIONING

Immune System to Brain Signaling Pathways

The field of psychoneuroimmunology is based on the existence of bidirectional communication pathways between the brain and the immune system. This implies that just as the CNS is capable of modulating immunity, the immune system can alter functioning within the CNS. Although researchers historically were first interested in pathways by which the brain affects immunity, the past 10–15 years have seen a groundswell of interest in the ways in which the immune system contributes to the development of psychopathology.

Underpinning this growing interest is an increasing appreciation for the multiple ways in which proinflammatory cytokines are able to signal the brain and change CNS function (Table 9–3). Although the brain was historically considered an "immune privileged" organ, protected from immune system activity by the blood–brain barrier, it is now clear that cytokines released in the periphery rapidly affect CNS functioning via at least four pathways that are not mutually exclusive (Raison et al. 2002). Proinflammatory cytokines injected into the abdominal cavity (intraperitoneal) have been shown to activate the vagus nerve, resulting in the independent production of proinflammatory cytokines within the CNS, especially in the hypothalamus and hippocampus, which are regions of central importance for the regulation of the ANS and emotion (Maier et al. 1998). Recent studies suggest that in addition to activating the vagus nerve, proinflammatory cytokines in the blood are able to signal the CNS by entering through "leaky" regions lacking a fully formed blood–brain barrier, such as the circumventricular organs, and, from there, to circulate in CSF to other brain regions (Rivest et al. 2000). Bloodborne proinflammatory cytokines can also communicate with the brain through intermediaries, without themselves entering the CNS parenchyma, for example, by acting on cells of the brain endothelium or choroid plexus and inducing the release of secondary messengers, such as prostaglandins and nitric oxide (Rivest et al. 2000). Finally, active transport across the blood–brain barrier provides another mechanism by which small quantities of proinflammatory cytokines may gain access to the CNS (Banks 2006; Banks et al. 1995; Plotkin et al. 1996).

Cytokines have effects on neurotransmitter turnover, neuroendocrine function, synaptic plasticity, and behavior (sickness behavior).

Once proinflammatory cytokines have gained access to the CNS through any of the routes outlined above, the inflammatory signal appears to be amplified by a cytokine network within the brain itself (Quan et al. 1999). It has already been noted that cytokines produced in the periphery stimulate the production of proinflammatory cytokines, such as IL-1, IL-6, and TNF-α, in a number of brain regions (Dantzer and Kelley 2007; Gatti and Bartfai 1993; Laye et al. 1994; Quan et al. 1999). Receptors for proinflammatory cytokines are found in the brain, especially in areas that are of central importance to homeostatic and emotional regulation, such as the hypothalamus and hippocampus (Benveniste 1998). Among neural cells, activated microglia are capable of producing significant amounts of proinflammatory cytokines, which, in turn, are potent activators of glial cells (Schobitz et al. 1994). Of interest, growing evidence suggests that nonimmunological stressors can induce cytokine expression in the brain, likely due in part to stress-induced activation of microglia (Frank et al. 2007). These data suggest that CNS cytokine pathways may participate in the response of an organism to a wide variety of environmental perturbations. Consistent with this finding, proinflammatory cytokines have been implicated in the modulation of circadian functioning, especially the sleep–wake cycle (Hohagen et al. 1993; Opp 2005).

Sickness Behavior and the Development of Depression in the Medically Ill

It has long been known that rates of major depression, as well as milder forms of mood disturbance, are many times more common in people with medical illnesses than in the general population (Evans et al. 1999). Although this has been typically ascribed to the overwhelming psychological stress frequently engendered by being seriously ill, more recent attention has been paid to the idea that immune system activation, which typically accompanies medical illness, may itself biologically predispose patients to depression (Raison and Nemeroff 2000). Evidence for this comes from the observation that rates of depression are significantly elevated in a wide variety of medical conditions including inflammatory and autoimmune disorders such as multiple sclerosis and rheumatoid arthritis, as well as illnesses such as cardiovascular disease, diabetes, and cancer, which are increasingly being recognized as having an important inflammatory component (Aggarwal et al. 2006; Blake and Ridker 2002; Evans et al. 2005). Moreover, prospective studies of conditions that are characterized by episodic immune dysregulation, such as multiple sclerosis or herpes infection, typically find that depression immediately precedes, rather than follows, episodes of disease exacerbation, suggesting that depressive symptoms associated with these conditions may result from underlying immune system activity rather than arising from a psychological reaction to exacerbation of the illness (Foley et al. 1992; Hickie and Lloyd 1995). Finally, as noted above, numerous groups have shown that when compared with similar patients without a current mood disorder, plasma concentrations of proinflammatory cytokines are significantly higher in medically ill patients with major depression versus those without (Raison et al. 2006). For example, IL-6 is elevated in depressed patients with cancer (Musselman et al. 2001b), and C-reactive protein is elevated in depressed patients with both acute coronary syndromes and chronic heart failure (Andrei et al. 2007; Lesperance et al. 2004).

More direct evidence that inflammatory processes may contribute to psychopathology, especially in the context of medical illness, comes from many studies in humans and animals demonstrating that

the administration of proinflammatory cytokines reliably induces changes in mood, cognition, and behavior similar to those commonly observed in patients with mood and anxiety disorders, as well as in psychophysical conditions such as CFS and fibromyalgia (Dantzer and Kelley 2007; Raison et al. 2006). This constellation of immune-induced changes, alternately referred to as "sickness syndrome" or "sickness behavior," consists of dysphoria, anhedonia, fatigue, social withdrawal, hyperalgesia, and cognitive and sleep disturbances, as well as decreases in appetite and libido (Kent et al. 1992). Although seen in response to infection, the full syndrome can be reproduced in animals and humans by administration of innate immune cytokines, such as IFN-α, IL-1, TNF-α, and IL-6, as well as IL-2, even in the absence of infection (Raison et al. 2002).

Results from studies utilizing positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) provide further evidence that peripheral cytokine activity can induce centrally mediated behavioral changes. These and other imaging modalities provide a means by which various behavioral alterations can be associated with specific brain regions. For example, during an fMRI task of visuospatial attention, in comparison with control subjects, patients administered IFN-α exhibited significantly greater activation of the dorsal anterior cingulate cortex (dACC) that highly correlated with the number of task-related errors (Capuron et al. 2005). Interestingly, increased dACC activity during cognitive tasks has also been demonstrated in patients vulnerable to mood disorders, such as those with high trait anxiety, neuroticism, or obsessive-compulsive disorder (Capuron et al. 2005). IFN-α has also been shown to lead to changes in basal ganglia metabolic activity as measured by PET that resemble those seen in Parkinson's disease. These changes also correlate with IFN-α–induced fatigue-related symptoms and may be a function of IFN-α effects on dopamine metabolism (Capuron et al. 2007).

Blocking cytokine activity with an IL-1 receptor antagonist, α-melanocyte-stimulating hormone, or IL-10 diminishes or prevents the development of sickness behavior in laboratory animals, even when such behavior develops as a result of psychological stress (Milligan et al. 1998). Similarly, etanercept, a novel agent that blocks TNF-α activity, has been reported to improve energy and overall emotional functioning in patients with rheumatoid arthritis, a condition characterized by increased proinflammatory cytokine activity (Mathias et al. 2000). Recently TNF antagonists have been shown to reduce depressive symptoms in patients with several autoimmune conditions (Persoons et al. 2005; Tyring et al. 2006). Further evidence that cytokine-induced behavioral toxicity is related to major depression comes from studies showing that in humans and animals, antidepressants are able to abolish or attenuate the development of sickness behavior in response to cytokine administration (Musselman et al. 2001a; Yirmiya et al. 2001).

Pathways by Which Inflammatory Cytokines Produce Neuropsychiatric Disturbance

In keeping with the observation that antidepressants mitigate emotional and behavioral symptoms resulting from immune system activation, significant evidence demonstrates that inflammatory cytokines affect neurotransmitters and neuroendocrine pathways that are regulated by currently available antidepressants and that have been implicated in the pathophysiology of depression and other stress-related neuropsychiatric disorders. It is increasingly recognized that these effects on the CNS and its outflow pathways may provide a physiological basis for the observation that immune activation frequently produces neuropsychiatric disturbance (Table 9–4).

Effects on Monoamine Neurotransmitters

In laboratory animals, the acute intracerebral administration of IL-1 produces a rapid and significant increase in norepinephrine and serotonin (5-HT) turnover in several brain regions (Linthorst et al. 1995a, 1995b). Far less is known about the effect of chronic proinflammatory cytokine exposure on functioning of monoamine systems in either animals or humans; however, cytokines, including IFN-α, have been shown to diminish 5-HT availability as a result of a cytokine-mediated enhancement in the activity of indoleamine 2,3-dioxygenase (IDO), an enzyme that shunts tryptophan metabolism away from 5-HT toward kynurenine and quinolinic acid, which is known to have neurotoxic properties (Dantzer et al. 2007; Raison et al. 2006). Tryptophan is the primary precursor of 5-HT, and depletion of tryptophan has been associated with the precipitation of mood disturbances in vulnerable patients (Moore et al. 2000). Moreover, significant evidence suggests that serotonergic neurotransmission is decreased in many patients with depression (Owens and Nemeroff 1998). It has also been shown that proinflammatory cytokines, via p38 mitogen-activated protein kinase (MAPK)–linked pathways, can increase the expression and function of synaptic reuptake pumps for serotonin (and norepinephrine), potentially further contributing to reduced synaptic availability of mood-relevant monoamines (Zhu et al. 2005, 2006). Of interest, the development of major depression in the context of chronic IFN-α treatment has been shown to correlate closely with decreased plasma concentrations of tryptophan, possibly as a result of increased IDO activity, consistent with the idea that cytokine-induced decrements in 5-HT availability may contribute to the development of depression (Capuron et al. 2002b). Furthermore, treatment with paroxetine attenuates the behavioral consequences of IFN-α–mediated tryptophan depletion (Capuron et al. 2003a). In addition to the effects of chronic cytokine exposure on serotonergic transmission, both IL-2 and IFN-α, when they are administered chronically, have been reported to alter dopamine metabolism, and as noted above, IFN-α has been shown to lead to altered metabolic activity in brain regions high in dopaminergic neurocircuits including the basal ganglia (Capuron et al. 2007; Lacosta et al. 2000; Shuto et al. 1997).

Effects on the Thyroid Axis

Medical illness is often associated with a state of functional thyroid deficiency known as euthyroid sick syndrome (ESS) (Papanicolaou 2000). In its early stages, ESS is characterized by normal thyroid-stimulating hormone (TSH) and thyroxine (T_4) levels, but by reduced levels of triiodothyronine (T_3), which is the more biologically active form of thyroid hormone. In later stages of ESS, T_4 levels are also decreased. Evidence suggests that proinflammatory cytokines promote this condition via direct effects on the thyroid gland, as well as by inhibition of enzymes responsible for peripheral conversion of T_4 to T_3, especially in the liver (Papanicolaou 2000). It is well known that decreased thyroid functioning is associated with the development of symptoms of depression, and functional abnormalities of the thyroid axis are observed in many patients with major depression who do not have clinically obvious thyroid disease (Musselman and Nemeroff 1996).

Effects on the Hypothalamic-Pituitary-Adrenal Axis

Inflammatory cytokines have well-described effects on the HPA axis that are consistent with changes frequently seen in patients with major depression, including increased production of CRH and cortisol and decreased tissue sensitivity to glucocorticoid hormones (Capuron et al. 2003a; Hasler et al. 2004; Pace et al. 2007; Silverman et al. 2005). Although cytokines have been shown to be capable of activating the HPA axis at multiple levels, with a resultant increase in glucocorticoid release, significant evidence suggests that a major final common pathway for cytokine activation involves

stimulation of CRH production in the paraventricular nucleus (PVN) of the hypothalamus (Besedovsky and del Rey 1996). Several lines of evidence suggest that this increase in CRH activity may contribute to cytokine-induced depression/sickness behavior. CRH has behavioral effects in animals that are similar to those seen in patients with depression and/or sickness syndrome, including alterations in appetite, activity, and sleep (Owens and Nemeroff 1991). Patients with major depression frequently demonstrate increased CRH production, as assessed by increased CRH in CSF, increased messenger RNA in the PVN, downregulated frontal CRH receptors, and a blunted adrenocorticotropic hormone (ACTH) response to CRH challenge (likely reflecting downregulation of pituitary CRH receptors) (Owens and Nemeroff 1993). Agents that block the CRH type I receptor have been shown to have antidepressant and anxiolytic effects in humans (Zobel et al. 2000). In animals, blocking CRH reverses some of the behavioral sequelae of proinflammatory cytokine administration (Dantzer 2001). Indirect evidence for a role of CRH in cytokine-induced depression in humans comes from a study in which individuals who developed depression during IFN-α administration exhibited significantly higher ACTH and cortisol responses to the first injection of IFN-α compared with control subjects (Capuron et al. 2003b). These findings suggest that sensitized CRH pathways may serve as a vulnerability factor for cytokine-induced behavioral changes.

In addition to direct stimulatory effects on CRH within the CNS, in vivo and in vitro studies suggest that inflammation may induce resistance to circulating glucocorticoids in nervous, endocrine, and immune system tissues (Pariante and Miller 2001; Raison and Miller 2003b). This is of great potential relevance, given the high rates of relative glucocorticoid resistance in HPA axis tissues (as assessed in vivo by the DST or the dexamethasone–CRH stimulation test) and the immune system (as measured in vitro) seen in patients with major depression and in animals and humans exposed to chronic and/or severe stressors (Holsboer 2000). Supporting a role for cytokines in the induction of glucocorticoid resistance is the observation that many chronic inflammatory conditions, including steroid-resistant asthma, rheumatoid arthritis, multiple sclerosis, and HIV infection, are characterized by a decrease in sensitivity to glucocorticoids (Raison et al. 2002). In HIV infection, glucocorticoid resistance has been shown to correlate with increased IFN-α plasma levels (Norbiato et al. 1998).

There are several mechanisms by which proinflammatory cytokines can disrupt glucocorticoid receptor (GR) function and contribute to glucocorticoid resistance. In addition to downregulating the expression of GR protein, proinflammatory cytokines have been found to increase the expression of the inert β isoform of the GR (Oakley et al. 1996). Exposure of cells that constitutively express both GR-α (the active isoform) and GR-β to either TNF-α or IL-1β in vitro results in a marked increase in GR-β production, which is associated with the development of glucocorticoid resistance, as evidenced by a significant reduction in dexamethasone-stimulated activity of a GR-sensitive reporter gene in cytokine-treated cells (Webster et al. 2001). That overproduction of the negative GR-β isoform has a clinically relevant effect on glucocorticoid sensitivity is suggested by several recent studies documenting that patients with a variety of inflammatory and immune system disorders, including asthma, ulcerative colitis, and chronic lymphocytic leukemia, whose conditions are resistant to steroid treatment demonstrate a significantly increased GR-β to GR-α ratio (Honda et al. 2000; Leung 1997; Shahidi et al. 1999; Sousa et al. 2000).

Another mechanism by which inflammatory cytokines may attenuate GR signal transduction and, hence, cause glucocorticoid resistance is through induction of inflammatory signaling pathways that directly influence GR function (Pace et al. 2007). For example, adding IL 1α to an in vitro preparation of mouse fibroblast cells has been shown to suppress the ability of dexamethasone to induce translocation of the GR from the cytoplasm to its site of action in the nucleus (Pariante et al. 1999). This IL-1α–mediated blockade of GR translocation from the cytoplasm to the cellular nucleus inhibits GR activity, as indicated by a decrease in the ability of dexamethasone to activate a glucocorticoid-sensitive reporter gene construct. The signaling pathways involved in this effect include p38 MAPK, which has been shown to phosphorylate the GR (X. Wang et al. 2004). Other inflammatory signaling

pathways have also been shown to alter GR function, including NF-κB, Jun N-terminal kinase (JNK), and STAT5 (Pace et al. 2007).

PSYCHOPHARMACOLOGICAL IMPLICATIONS OF BRAIN–IMMUNE SYSTEM INTERACTIONS

Antidepressants and Immune System Activation

The term *antidepressant* has been depicted, more than once, as a misnomer, given the wide spectrum of activity evinced by these pharmacological agents. Adding to this activity spectrum are findings that antidepressants have clear immunomodulatory effects in animals and humans. In general, antidepressants have been found to decrease immune responsiveness (Kenis and Maes 2002). Because of this, these agents may be of benefit for a wide range of symptoms that arise in the context of immune activation. Of special interest, given the ability of inflammatory cytokines to induce sickness behavior and/or major depression, a number of antidepressants have been reported to attenuate proinflammatory cytokine production, not just from peripheral immune cells (Maes 1999) but also from within the CNS, where desipramine has been reported to diminish TNF-α release within the locus coeruleus (Ignatowski and Spengler 1994). Interestingly in this regard, the antidepressant efficacy of desipramine during the forced-swim test has been shown to be dependent on reductions in neuronal production of TNF-α and can be reversed by exogenous TNF-α coadministered with the antidepressant (Reynolds et al. 2004). Desipramine has also been shown to lower peripheral TNF-α production in response to lipopolysaccharide (LPS) administration—an effect that was associated with abrogation of the depressive-like behavioral effects of LPS (Shen et al. 1999). The heterocyclic antidepressant bupropion has been similarly noted to markedly diminish TNF-α production following LPS administration in animals (Brustolim et al. 2006). Of note, concomitant with attenuating proinflammatory cytokine production, antidepressants enhance production of the anti-inflammatory cytokine IL-10 (Maes et al. 1999d).

In addition to potential direct effects on cytokine production, antidepressants impact neuroendocrine and neurotransmitter systems in ways known to diminish inflammatory activity. For example, all antidepressants appear to downregulate the overproduction of CRH and cortisol that frequently occurs in the context of major depression. Much evidence suggests that this downregulation results from the ability of antidepressants to enhance glucocorticoid signaling via increased glucocorticoid receptor functioning, which, in turn, leads to a restoration of glucocorticoid-mediated inhibitory control on the HPA axis (Pariante and Miller 2001). Because CRH has been shown to directly stimulate proinflammatory cytokine production, antidepressants may modulate inflammatory activity in part by diminishing CRH production. Glucocorticoid receptors, in addition to inhibiting CRH release in the hypothalamus, also mediate the well-characterized anti-inflammatory properties of glucocorticoids. It is likely that antidepressants decrease inflammatory activity in part via their ability to potentiate glucocorticoid receptor functioning (Pariante and Miller 2001). Antidepressants also normalize the hyperactivity of the locus coeruleus and SNS frequently seen in major depression (Ressler and Nemeroff 1999). Because catecholamines have been shown to enhance proinflammatory activity, the ability of antidepressants to normalize catecholaminergic functioning would be expected to diminish inflammatory activity. Finally, antidepressants are known to enhance functioning in intracellular second-messenger systems (such as the cyclic adenosine monophosphate [cAMP] cascade) known to suppress the activation of genes that encode for the production of proinflammatory cytokines (Duman et al. 2001).

Whatever the mechanism, it is clear from studies in animals and humans that antidepressants effectively diminish many physical, emotional, cognitive, and behavioral symptoms that arise in the context of immune system activation (Capuron et al. 2002a). In animals, pretreatment with a number of antidepressants has been shown to prevent or diminish the development of sickness syndrome in response to either pathogen or cytokine exposure (Yirmiya et al. 2001). In humans, pretreatment with

an antidepressant has been shown in a double-blind, placebo-controlled trial to significantly reduce the development of major depression in patients receiving high doses of the proinflammatory cytokine IFN-α for the treatment of malignant melanoma (Musselman et al. 2001a). In this study, 45% of patients receiving placebo had developed major depression within 3 months of starting IFN-α, compared with only 11% receiving the selective serotonin reuptake inhibitor paroxetine. Of interest, however, paroxetine was not equally efficacious for all the symptoms associated with sickness syndrome. Specifically, the antidepressant significantly reduced the symptoms of depressed mood, anxiety, and poor cognitive functioning but was no more effective than placebo in the treatment of somatic or neurovegetative symptoms, such as fatigue and anorexia, suggesting that these symptom domains may have nonoverlapping etiologies (Capuron et al. 2002a). Consistent with this finding, neurovegetative symptoms tended to develop early (and to persist) in the course of IFN-α treatment in a majority of patients, whereas symptoms of depressed mood, anxiety, and cognitive disturbance tended to develop insidiously over weeks or months of treatment in a smaller percentage of patients (Trask et al. 2000). The success of pretreatment strategies in preventing the development of neuropsychiatric disorders in medically ill patients at high risk for mood disorders is intriguing and suggests that prophylactic antidepressants may be considered in other medical contexts, such as for patients about to undergo treatment with radiation and/or chemotherapy, as well as for patients about to undergo major surgery.

There are also data to suggest that antipsychotics, although not as well studied as antidepressants, may have immunological effects relevant to their mechanism of action. Intriguing in this regard is a study demonstrating increased antipsychotic efficacy in patients with schizophrenia treated with the combination of the cyclo-oxygenase-2 inhibitor celecoxib, an anti-inflammatory drug, and risperidone versus risperidone plus placebo (Müller et al. 2002).

Immune System Interventions for Behavioral Symptoms

Given that proinflammatory cytokines induce depressive syndromes, and given that many medically healthy patients with depression appear to demonstrate increased inflammatory activity, it is logical to inquire as to whether agents that directly target inflammatory mediators, such as anti-inflammatory agents and drugs that disrupt cytokines and their cytokine signaling pathways (e.g., NF-κB, p38 MAPK), might be of benefit in the treatment of both stress- and immune-related neurobehavioral disorders. Indeed, in a recent double-blind, randomized, placebo-controlled study, patients with major depressive disorder who took celecoxib as an adjunct to reboxetine experienced a significantly greater therapeutic benefit than those taking reboxetine alone (Müller et al. 2006). In animal models, endogenous inhibitors of proinflammatory cytokines, such as the soluble receptor antagonist for IL-1 (sIL-1ra), have been reported to attenuate or abolish sickness symptoms following endotoxin or cytokine administration (Maier and Watkins 1998). Of interest, in addition to direct anti-inflammatory activities, sIL-1ra also blocks many of the sequelae of psychological stress in rodents. For example, direct injection of sIL-1ra blunts HPA axis responses to psychological stressors, such as restraint, and prevents stress from causing learned helplessness (a frequent animal model for depression) (Maier and Watkins 1998). Administration of IL-ra has also been shown to reverse the inhibitory effects of stress on the expression of brain-derived neurotrophic factor in the dentate gyrus of the rat hippocampus (Barrientos et al. 2003). Of note, mice whose TNF-α receptor genes have been knocked out exhibit an antidepressant phenotype and are resistant to anxiety-conditioning paradigms and virus-induced anxiety behaviors (Silverman et al. 2004, 2007; Simen et al. 2006). Of further relevance to the behavioral effects of targeting cytokines such as TNF-α are data demonstrating improvements in behavioral symptoms in patients with inflammatory and autoimmune disorders who are receiving therapies that block TNF-α activity (e.g., etanercept, infliximab). For example, significant improvement in emotional well-being has been observed in patients treated with these agents for psoriasis, rheumatoid arthritis, and ankylosing spondylitis (Braun et al. 2007; Katugampola et al. 2007; Mathias et al. 2000). Most relevant, however, was a recent double-blind, placebo-controlled

trial of etanercept for the treatment of psoriasis, in which patients who received active drug exhibited significantly greater improvement in depressive symptoms compared with placebo-treated patients, independent of the effect of the drug on disease activity (Tyring et al. 2006). Although the risk of side effects with cytokine antagonists is relatively low, when adverse events do occur, they can be serious, including life-threatening infections, reactivation of tuberculosis, congestive heart failure, lymphoma, induction of autoantibodies, and a lupus-like reaction.

Treatment of chronic pain, with or without the presence of mood symptoms, is another burgeoning area of translational drug discovery. Data from animal models suggest that proinflammatory cytokines, specifically IL-1 and TNF, play a pivotal role in the creation and maintenance of neuropathic pain (Marchand et al. 2005; Moalem and Tracey 2006). These findings led to the hypothesis that IL-10, an anti-inflammatory cytokine, may prove to be a promising therapeutic option via attenuation of IL-1 and TNF activity. Indeed, it has been shown in animal studies that IL-10, via intrathecal IL-10 gene therapy, is effective in the control of both acute and chronic pain (Ledeboer et al. 2007; Milligan et al. 2006).

It has been suggested that the increased prevalence of major depression observed in the Western world over the past half-century may be caused, at least in part, by a decrease in the consumption of omega-3 fatty acids (Maes et al. 1999a), which are well known to have anti-inflammatory effects via the inhibition of prostaglandins and proinflammatory cytokines. Consistent with this, populations that consume diets high in omega-3 fatty acids (found especially in fish) appear to have diminished rates of major depression (Tanskanen et al. 2001). Conversely, patients with major depression have been reported to have decreased serum concentrations of omega-3 fatty acids (Maes et al. 1999a; Tiemeier et al. 2003). These observations suggest that the administration of omega-3 fatty acids might be beneficial to patients with mood disorders. Preliminary studies have indeed shown that adjunctive administration of omega-3 fatty acids under double-blind, placebo-controlled conditions significantly improves persistent mood symptoms in patients with depression (Peet and Horrobin 2002) and decreases disease relapse in patients with bipolar disorder (Stoll et al. 1999). Low omega-3 fatty acid levels may also contribute to the increased rates of depression in the medically ill, in particular in patients with cardiovascular disease. In a study evaluating patients 2 months after an acute coronary event (myocardial infarction or unstable angina), patients with comorbid major depression had significantly lower levels of omega-3 fatty acids (Frasure-Smith et al. 2004) than their nondepressed counterparts. Given that low omega-3 fatty acid levels are associated with mood disorders (Parker et al. 2006), in addition to increased levels of inflammation (Simopoulos 2002), an increased risk for coronary artery disease (Kris-Etherton et al. 2003), and fatal arrhythmias (Leaf et al. 2003), further studies evaluating the effects of omega-3 supplements in at-risk populations are warranted.

Chapter 10. Brain Imaging in Psychopharmacology

BRAIN IMAGING IN PSYCHOPHARMACOLOGY: INTRODUCTION

Functional brain imaging **refers to a class of techniques that noninvasively measure correlates of neural activity. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) are the two technologies most commonly used today to study the human brain "in action." The explosion of information about human brain function occurring in the past decade has resulted in large part from these two techniques. As will be described in this chapter, PET imaging has made considerable contributions to our understanding of the mechanisms of drug action, mostly through application of radiopharmaceutical labeling of neurotransmitter receptors. fMRI, on the other hand, has gained rapid acceptance because of the widespread availability of magnetic resonance imaging (MRI) scanners, the lack of radioactive exposure, and the better image resolution offered.**

The advent of neuroimaging techniques for probing in vivo human brain function undoubtedly represents a major milestone in the scientific endeavor of understanding the relationship between mental disorders and the brain. The development of the specific tools employed in brain mapping, although fairly recent, has already produced an impressive amount of experimental data, whose potential informational content is most likely being underexploited at the present time (Van Horn and Gazzaniga 2002). The neuroimaging approach offers the unique possibility of noninvasively investigating the neurophysiological, neuroanatomical, and neurochemical correlates of the living, performing human individual. As a complement to classical neuropsychology, this approach represents an unprecedented break from the necessity of lesion studies for the inference of structure–function relationships in the human brain. Furthermore, a neuroimaging assay can typically acquire data simultaneously from the entire cerebral system, thereby allowing the study of the distributed processing properties of the brain (Friston 2002). Those properties represent a fundamental and distinctive feature of massively parallel processing systems but are not easily penetrated with the standard neurophysiological methods employed in the animal, such as intracortical electrode recording, which can probe only a limited number of sites simultaneously.

NEUROIMAGING TECHNIQUES

Neuroimaging **is a generic term for a number of techniques and methods aimed at detecting meaningful information through the acquisition of brain images of different kinds. The presentation of different classification criteria may help the reader to get a sense of this rich but often confounding landscape. A first classification may be technology based:**

- MRI
- PET
- Single photon emission computed tomography (SPECT)
- Electroencephalography (EEG)
- Magnetoencephalography (MEG)

Each of the above technologies requires different hardware, and each measures different physical quantities. It should be noted that whereas PET and SPECT employ radioactive tracers that limit their

repeated use on the same subject, the other techniques are noninvasive and therefore allow more latitude in regard to experimental design and the subsequent statistical treatment of the data. MRI and PET/SPECT scanners are able to implement different imaging protocols, according to the specific acquisition modality employed (MRI) or the nature of the injected radioisotope (PET/SPECT). More recently, the availability of combined PET–computed tomography (PET–CT) and PET–MRI scanners has yielded an added dimension to our capacity to understand human brain in action (Blodgett et al. 2007).

The neurally related variable that is actually imaged may provide an alternative classification framework:

- *Vascular (or hemodynamic) effects engendered by neural activity:* PET ($H_2{}^{15}O$), fMRI (blood oxygenation level–dependent [BOLD] contrast, perfusion imaging), SPECT
- *Metabolic demand:* PET (^{18}fluorodeoxyglucose)
- *Receptor density:* PET/SPECT (radioligands)
- *Neurochemistry:* Magnetic resonance spectroscopy (MRS)
- *Connectivity pathways:* MRI (diffusion tensor imaging), fMRI-based functional connectivity analysis
- *Surface electromagnetic effects of brain activity:* EEG/MEG
- *Morphometry of brain structures:* MRI

We begin this chapter with current thoughts on the physiological basis of functional imaging and the phenomenon of neural activation it attempts to study (referred to as "neurovascular coupling") and then proceed to examine the two major functional imaging modalities of relevance to psychiatry—PET and fMRI. The section on fMRI will also incorporate basic principles of MRI. We end the chapter with a brief review of magnetic resonance (MR)–based structural imaging modalities and how they might confer newer insights into the understanding of mental illness and development of newer treatments. The focus is intended to be on how these imaging methods are used to better understand psychopharmacology. More details on individual disorders will be available in their respective sections.

FUNCTIONAL IMAGING AND CORRELATES OF NEURAL ACTIVITY

It has been known for more than 100 years that blood flow to the brain increases in a regionally specific manner, according to mental activity. The father of modern psychology, William James, was aware of observations relating regional brain pulsation to mental activity (James 1890). Paul Broca, known primarily for his observations on the effects of left frontal lesions on language, performed several experiments relating regional brain temperature to cognitive function (Broca 1879). But it was not until the 1950s, when Seymour Kety and Louis Sokoloff developed the autoradiographic technique for quantitatively measuring regional blood flow, that specific cognitive functions could be directly mapped in the living brain (Kety 1965).

Both PET and fMRI rely on the fact that blood flow increases in areas where neuronal activity increases, and most studies implicitly assume the validity of this relationship. It is easy to see the link in terms of an increased metabolic demand. The activation of a neural circuit is a complex network of electrochemical processes that requires energy. The most demanding processes, in terms of energy expenditure, are those related to synaptic activity, which results in breakdown of energy stores in the neuron in the form of adenosine triphosphate (ATP) molecules. To replace the ATP energy stores degraded by the increased metabolic demand, a surge in the concentration of glucose and oxygen is necessary, which results in increased blood flow to the activated region. It is this vascular or *hemodynamic* response to neural activity—that is, the variation in regional cerebral blood flow (rCBF)—that is the quantity actually measured in the majority of brain activation studies with fMRI and PET/SPECT (Arthurs and Boniface 2002; Jueptner and Weiller 1995). Thus, the hemodynamic response represents an *indirect* assay of neural activity (Villringer and Dirnagl 1995). It is important to note that the hemodynamic response *lags behind* the actual neural activity by a few seconds. The hemodynamic response is also blurred in the spatial domain compared with the underlying neural activity. This imposes limits on the spatiotemporal resolution of blood flow methods, independently of technology

improvement.

A special caveat should be noted concerning the interpretation of rCBF results. The measurement of task-related variations of rCBF does not provide any clear indication about the nature of the underlying neural activity (i.e., whether it is excitatory or inhibitory), although hypotheses have been proposed for and argued against a bias favoring excitatory contributions (Heeger et al. 1999; Tagamets and Horwitz 2001; Waldvogel et al. 2000). The construction of specific inferences about the actual state of activity —actively excited or actively inhibited—of brain regions showing an increase in rCBF during an experimental task would require the integration of information from many different sources (e.g., electrophysiology, neurochemistry, cytoarchitectonics).

In summary, despite the fact that the physiological and biochemical processes linking the neural activity and the hemodynamic response have not been clarified yet, the empirical relationship between these parameters appears both reliable and reproducible in a variety of contexts. The validity of fMRI measurements of signal change as an assay of neural activity has been documented using electrophysiological techniques such as neuronal field potentials (Logothetis et al. 2001).

POSITRON EMISSION TOMOGRAPHY

PET was developed from in vivo autoradiographic techniques. In an autoradiographic procedure, an animal is typically injected with a biologically interesting compound synthesized with a radioisotope (e.g., ^{3}H). When the animal is sacrificed, the local tissue radioactivity is easily quantified. Although autoradiography yields exquisitely detailed pictures of brain activity, it can only be applied in animals, and the animals must be sacrificed to obtain the brain tissue. Although these techniques were in use in the 1950s and 1960s, the development of an in vivo method applicable to humans awaited technological advancements from the "silicon revolution"—namely, the availability of high-quality inexpensive crystal detectors and the huge advancements in computing power realized in the late 1970s.

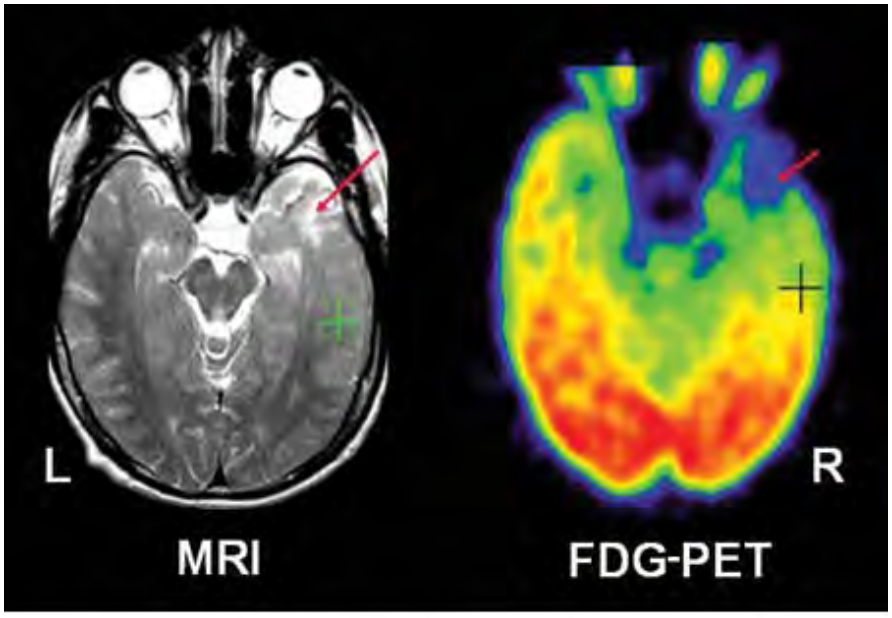
PET requires three basic technologies: the production of positron-emitting compounds, the ability to detect simultaneously emitted gamma rays, and the computational power to reconstruct the sources of emission. Positrons, or positively charged electrons (antimatter), have a particular advantage over other radioactive compounds. When a positron encounters an electron, the two annihilate each other, and their collective energy is transformed into two high-energy photons that are emitted in exactly opposite directions. Because the photons travel 180° apart, it is easy to arrange a ring of detectors to determine where the annihilation occurred. When two detectors are activated simultaneously, then one knows that the emission occurred somewhere along the line connecting the two detectors. By collecting the counts over a period of time, say 60 seconds, and over a full sphere surrounding the subject's head, it becomes possible to reconstruct the geometry of the source.

Positrons are produced indirectly, through the radioactive decay of particular isotopes. The most commonly used isotopes (carbon-11 [^{11}C], oxygen-15 [^{15}O], fluorine-18 [^{18}F], nitrogen-13 [^{13}N]) are produced in a cyclotron by the bombardment of targets with high-energy protons. This results in a gas (e.g., $^{15}O_2$), which can then be used in any chemical reaction (e.g., oxidation–reduction reaction with product $H_2{}^{15}O$). After appropriate purification procedures, these compounds can then be injected intravenously into a human subject, and they flow to the brain in about 20 seconds. The isotope undergoes radioactive decay by positron emission, and the half-life depends on the particular isotope (e.g., 2 minutes for ^{15}O).

Because the photons emitted during positron decay are fairly high in energy (511-keV gamma rays), they tend to pass through matter with relative ease. A specialized detector, called a scintillation detector, is required to accurately count the decays in a directional fashion. PET scanners consist of rings of these detectors arranged in parallel planes. An individual detector would be constructed from a scintillating crystal, either bismuth germanate (BGO) or lutetium oxyorthosilicate (LSO), and amplification electronics. When a gamma ray enters the crystal, it loses its energy through either the photoelectric or Compton effect, which results in the production of electrons. These electrons further

interact with the crystal, resulting in the production of visible wavelength photons. These photons are then detected and amplified by a photomultiplier tube and converted into an electrical pulse. A "coincidence circuit" allows for the identification of the detector that picks up the 180°-emitted gamma ray.

Depending on the injected molecule, a particular regional distribution will occur. In the case of $H_2{}^{15}O$, it will follow the rCBF. Other compounds will cross the blood–brain barrier and bind to specific receptors, in which case the distribution of radioactivity will reflect receptor concentration. Fluorodeoxyglucose-18 (^{18}FDG), a commonly used tracer, is metabolized by hexokinase during glycolysis, like glucose. Unlike glucose-6 phosphate, ^{18}FDG is not metabolized further and thus accumulates intracellularly, yielding a measurement of local metabolic activity (Kennedy et al. 1976; Reivich et al. 1979).



Types of PET Studies

Most PET neuroimaging studies can be grouped into one of three categories: metabolic, blood flow, or receptor studies.

Metabolic PET Studies

Metabolic studies use ^{18}FDG to measure regional glucose metabolism. ^{18}FDG, like all ^{18}F compounds, has the advantage of a relatively long half-life (110 minutes). This allows the synthesis to be performed in one location, the subject injection in another location, and the scanning in yet another location. In fact, one can have a subject doing a particular task in a location remote from the PET scanner and inject ^{18}FDG, which will be trapped in brain regions according to the local metabolic rate. This has an obvious advantage in situations in which placing the subject in the scanner would alter the conditions of the task. For example, ^{18}FDG is used commonly in sleep studies. The main disadvantage is that the long half-life results in effectively no temporal resolution. This offers a time-averaged snapshot of a particular brain state, and the state is averaged over 20–60 minutes. Figure 10–1 shows functional localization of an epileptic focus in the right temporal lobe during presurgical workup.

FIGURE 10–1. Functional localization of an epileptic focus in the right temporal lobe during presurgical workup using magnetic resonance imaging (MRI) and fluorodeoxyglucose positron emission tomography (FDG-PET).

Most of the FDG uptake studies are based on the assumption that the glucose uptake and neural activity at the synaptic level might be coupled. A caveat must be borne in mind when evaluating studies using FDG-PET. Glutamate is the main excitatory neurotransmitter in the brain, and it is removed from the synapse through a process of uptake by astroglial tissues, thus terminating neural activation (Magistretti and Pellerin 1999). But recent studies have shown that uptake of glutamate by astroglia can by itself stimulate glucose (and FDG) uptake (Magistretti 2006). In fact, deactivation might actually be coupled with increased glucose uptake in a variety of conditions (Magistretti 2006). Thus, the same problems that accompany studies of fMRI—i.e., whether the signal is actively excitatory versus actively inhibitory—are present in FDG-PET studies as well.

Blood Flow PET Studies

Blood flow studies use $H_2{}^{15}O$ to measure changes in local brain blood flow (Herscovitch et al. 1983; Mintun et al. 1984). As noted earlier, blood flow is an indirect measure of local synaptic activity. Because ^{15}O has a short half-life (2 minutes), several administrations can be performed in one session. A typical $H_2{}^{15}O$ study would have 8–16 injections and scans for each subject. The experimental design would manipulate the task that the subject performs during each scan. Each scan lasts about 1 minute, with 8–10 minutes between scans (5 half-lives). $H_2{}^{15}O$ studies not only allow for multiple conditions to be studied, but they also allow for the repetition of conditions, increasing statistical power. The main disadvantage is that because of the short half-life, the $H_2{}^{15}O$ must be produced reliably and in close proximity to the scanner.

Receptor-Mapping PET Studies

Receptor studies use radioligands—chemicals incorporating a positron-emitting isotope into a molecule whose pharmacokinetics are already known. Ideally, these ligands bind specifically to one receptor type. Most of these studies are of the mapping type, which shows the distribution of a particular receptor in the brain (e.g., dopamine type 2 [D_2] receptor). Here, the measured radioactivity reflects both the local concentration of receptors (B_{max}) and the affinity of the ligand for the receptor (measured by K_D, the equilibrium dissociation constant). If the ligand acts as a competitive antagonist, then the *apparent* affinity is also affected by the concentration of the endogenous neurotransmitter. The analysis can be simplified by considering the ratio of B_{max} to K_D, termed the *binding potential* (BP). Ligands undergo both specific and nonspecific binding. Typically, one is interested only in the specific binding (i.e., to the receptor of interest). Use of a reference tissue that is known to have a low receptor concentration allows one to subtract out the nonspecific binding (e.g., the cerebellum has a low concentration of D_2 receptors). In this case, the difference in distribution for the two tissues is directly proportional to the BP. Ligands require a more involved synthesis than either water or ^{18}FDG, and their use is a race against the clock as the isotope decays. The end product must meet several requirements: high specific activity (amount of radioactivity per mole), high radiochemical purity, and sterility. ^{18}F ligands are easier to synthesize because of their long half-life, but ^{11}C ligands (20-minute half-life) have a higher potential for biological relevance. These will be discussed in the next section, which addresses psychopharmacological applications of PET tracers and ligands.

Clinical Applications of PET and SPECT in Psychopharmacology

PET-based receptor imaging has provided us with a window to view the complex functioning of brain systems involved in mediating treatment response to psychopharmacological agents. A snapshot of available radionuclide-binding modalities is provided in Table 10–1. Using PET-based radioligands, it has been possible to visualize density, distribution, and occupancy of neural receptors and transporters before, during, and after drug therapy (Talbot and Laruelle 2002). Details about use of neuroimaging methods in individual psychiatric disorders will be described in detail in later chapters pertaining to

these disorders. In the following sections, specific examples will be provided to illustrate the use of imaging methods to answer pertinent questions of relevance to psychopharmacology.

Neurotransmitter Synthesizing Systems

Appropriate availability of neurotransmitters and neuromodulators is essential to normal neurological and psychological function. Dysfunction or degeneration of neurons that synthesize these substances can lead to various disorders. For example, Parkinson's disease is caused by selective degeneration of the dopamine-synthesizing neurons of the nigrostriatal system. Uptake of [^{18}F] DOPA, which selectively labels aromatic L-amino acid decarboxylase (AADC), a critical enzyme in the synthesis of dopamine, has been used to estimate both the number of surviving cells and AADC activity among nigral neurons, thus providing a tool to understand the connection between dopamine dysfunction and clinical symptom evolution (Cropley et al. 2006; Ravina et al. 2005). PET scanning using [^{11}C] methyl-L-tryptophan, which is a marker of serotonin (5-HT) synthesis, is being used in identifying overactive serotonin-synthesizing systems in differentiating epileptogenic from nonepileptogenic lesions in tuberous sclerosis (Luat et al. 2007) prior to neurosurgery. In a similar vein, recent functional imaging techniques have combined with neurosurgical treatments such as deep brain stimulation to study brain imaging biomarkers of treatment response (Carbon and Eidelberg 2002).

Neurotransmitter Binding Sites

PET imaging has been used to identify binding sites of neurotransmitters of relevance to psychiatric disorders, in order to characterize patients and inform treatment decisions based on mechanisms of drug action. For instance, studies with ligands that bind to D_2 receptors have informed us that lower binding affinity, faster dissociation, and optimal occupancy at usually prescribed doses of D_2 receptor antagonists might form the basis of atypical antipsychotic drug action (Kapur and Remington 2001). Studies reporting increased binding of serotonin type 2A ($5\text{-}HT_{2A}$) receptors using agents such as ^{18}F-altanserin in frontal cortex (Brodmann area [BA] 9) and their association with increased pessimism and self-injurious and suicidal behavior have added to our understanding of depression (Meyer et al. 2003). Alterations in the function of γ-aminobutyric acid (GABA) systems in posttraumatic stress disorder (PTSD) and panic disorder have been reported based on decreased binding of (^{123}I)iomazenil to benzodiazepine receptors in the BA 9 region of these patients (Bremner et al. 2000).

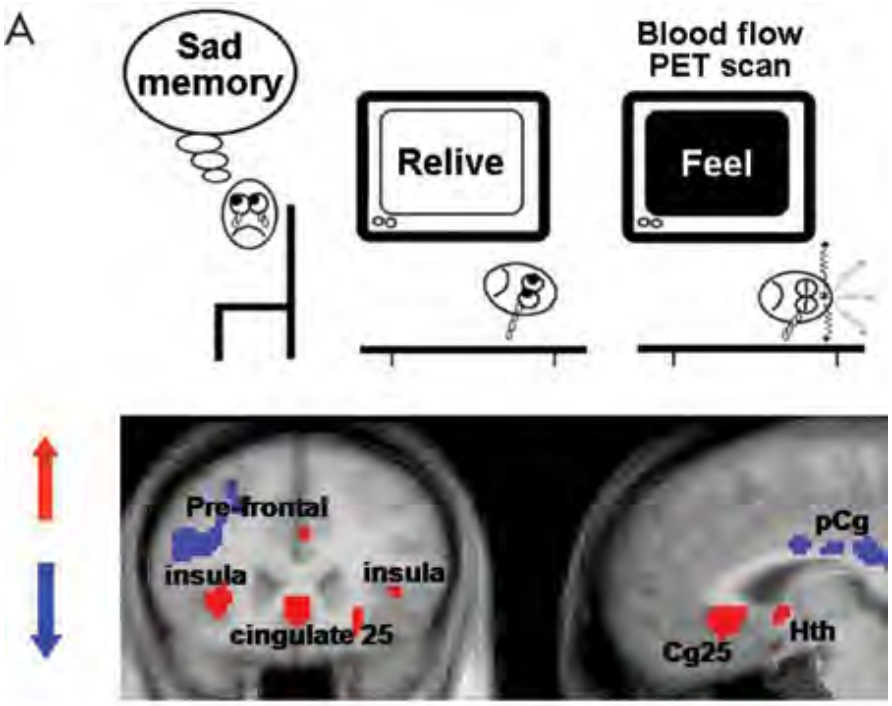
Neurotransmitter Reuptake Site Binding Studies

Drugs that bind to and inhibit the serotonin reuptake transporter (SERT) have been shown to be associated with symptomatic recovery from depression in a large number of patients (Nemeroff 2007). Radioligands that show high specificity for binding to SERT, such as [^{11}C] 3-amino-4-(2-dimethylaminomethyl-phenylsulfanyl)-benzonitrile (^{11}C DASB), have been used to study the site occupancy levels of selective serotonin reuptake inhibitors (SSRIs) and how these values correlate with

clinical efficacy (Meyer 2007). These methods have led to reformulation of clinical algorithms in the management of depressive disorders. Suicide remains a serious risk among all psychiatric patients, and the role of SERT in the expression of suicide has been studied using PET ligands (Purselle and Nemeroff 2003). Dopamine transporter (DAT) ligands have also been used to study cognitive and motor dysfunction in Parkinson's disease (Cropley et al. 2006; Ravina et al. 2005), and the same methods are currently being applied to investigate conditions such as attention-deficit/hyperactivity disorder (ADHD).

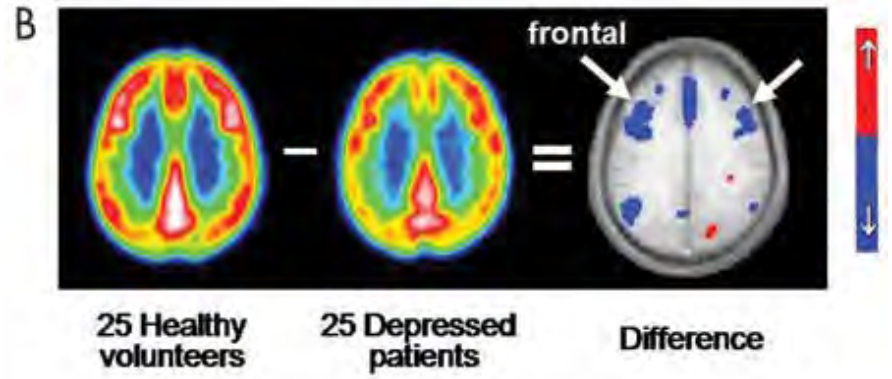
Neurotransmitter Autoreceptor Binding Methods

Synaptic turnover of serotonin secretion is regulated by two processes—by SERT-mediated reuptake and by negative feedback mediated through serotonin type 1A (5-HT_{1A}) autoreceptors. Downregulation of 5-HT_{1A} receptors may be associated with antidepressant efficacy and might also explain the delay in the onset of clinical response after being started on SSRIs (Blier and Ward 2003). Radioligands such as [^{11}C] WAY-100865 have been used to study the dynamics of 5-HT_1 receptors (Fisher et al. 2006). This methodology has also made contributions to better understanding how serotonergic system imbalances disrupt mood-regulating neural circuitry, resulting in depressive disorders (Fisher et al. 2006).



Pathological Cerebral Deposits

Degenerative disorders such as Alzheimer's disease have acquired critical relevance, given the larger proportion of aging population in the modern society. Since the pathological changes associated with neurodegeneration (such as beta-amyloid deposits, neurofibrillary tangles, and decreased metabolic activity) often precede clinical disease by several decades, early identification of these changes is of paramount importance. Three different ligands have been reported recently, all of them with the ability to detect intracerebral beta-amyloid deposition with high accuracy using PET radiotracer technology: [^{18}F] FDDNP (Small et al. 2006), [^{11}C] PIB (Pittsburgh Compound–B) (Klunk et al. 2004), and [^{11}C] SB (Ono et al. 2003). Such compounds have potential clinical applications in that they may help identify patients with mild cognitive impairment (MCI) who are at increased risk of converting to dementia (Mathis et al. 2005).



PET Tracers of Cerebral Metabolism and Blood Flow

PET has been used to assess functional activity of brain regions, both in the resting state and in response to various stimuli. The methods used include use of FDG-PET and radioactive [^{15}O] H_2O-PET to study metabolic activity and blood flow, respectively. Figure 10–2A shows a picture of increased cerebral blood flow to paralimbic regions during a sad mood induction task (to be described later) using H_2O-PET. In contrast, Figure 10–2B shows metabolic activity differences among depressed versus healthy patients using FDG-PET. These modalities have been effectively used to study a variety of mental phenomena and have been of considerable benefit in enhancing our understanding of psychiatric disorders. Of particular interest have been studies using PET to understand the biological basis of schizophrenia (Fujimoto et al. 2007; Lange et al. 2005), bipolar disorder (Post et al. 2003), depression (Mayberg 2003b; Neumeister et al. 2004), substance abuse and craving (Kilts et al. 2004), PTSD (Bremner 2007), ADHD (Schweitzer et al. 2003), and Alzheimer's disease (Small 1996). Most of the studies of psychiatric disorders have shown generally similar patterns of resting blood flow and metabolic abnormalities in using PET. That said, such identified patterns have not yet proven adequately consistent to warrant use of PET as a diagnostic procedure in an individual patient. Notably, only resting-state FDG-PET scanning has undergone repeated sensitivity and specificity testing to be considered useful and reliable for the diagnosis of Alzheimer's disease in patients with progressive cognitive disturbance and presumed dementia (Silverman et al. 2002). Nonetheless, research studies using these methods have provided considerable new insights into disease pathophysiology as well as mechanisms mediating treatment response (Erritzoe et al. 2003; Evans et al. 2006; Mayberg 2003a; Roffman et al. 2005).

MAGNETIC RESONANCE IMAGING

The basis of MRI technology rests on the magnetic properties of the hydrogen atom, which, as a component of water, is found ubiquitously in organic tissues (water constitutes roughly 80% of brain weight). The nucleus of a hydrogen atom, a single proton, is characterized by an intrinsic magnetic moment, called *spin.* The protons in tissue are normally oriented in random directions, but if an external

magnetic field is applied, they will tend to align with the field. Quantum mechanics and statistical physics dictate that spins can orient either in the direction of the applied field (*parallel*) or in the direction opposite to it (*anti-parallel*), but on average the parallel orientation will gain a weak majority. This situation will result in a net magnetic moment induced by the external field in the tissue; in other words, the tissue will become slightly magnetized. The external (or *main*) field in an MR environment is provided by a powerful electromagnet whose intensity is typically 1.5 tesla for clinical scanners (for comparison, the electromagnets used in car demolition lots have a similar strength), and up to 7 tesla for human research scanners. The intensity of the induced magnetization is dependent on the proton distribution (i.e., on the local molecular characteristic of the tissue). Although this induced magnetization could, in principle, provide a contrast signal resolving different type of tissues (e.g., gray matter, white matter, cerebrospinal fluid) into an image of anatomical detail, the magnitude of this effect is in practice so small that it does not lend itself to direct measurement.

The way in which MRI actually recovers its signal is by first perturbing the examined system. This instrumental perturbation is performed by applying short radiofrequency (RF) pulses that, when appropriately tuned, are able to transiently tip the orientation of the spins away from the applied magnetic field. However, the tendency of the spins is to return to the orientation coherent with the applied magnetic field, given that the latter state is characterized by a lower energy. The relaxation process occurs through the emission of an RF wave that is detected by the same RF hardware that emits the excitation pulses. In MR terminology, this is referred to as the RF coil, which has the form of a small cylindrical cage that surrounds the subject's head in the scanner. The emitted RF wave—or, more precisely, the temporal signature of its decay as the excited spins relax—constitutes the actual MR signal and depends on the molecular characteristics of the local tissue, as well on the particular sequence of excitation pulses employed. The details of the physics that specify how appropriate pulse sequences can be engineered to acquire images of the brain system with different physiological meaning are beyond the scope of this discussion, and the interested reader is directed elsewhere (e.g., Buxton 2002).

The spin relaxation measured with MRI can be decomposed into longitudinal and transverse components, which are only partially related. The measurement of the relaxation time of the longitudinal component, called *T1,* provides images in which the contrast between different types of tissue (notably, gray matter, white matter, and cerebrospinal fluid) is maximized. Such *T1-weighted images* are capable of defining the anatomy of the living brain with great precision and are therefore used as an anatomical reference for most of the neuroimaging studies. An image of the entire brain, with a resolution, or voxel size, of 1 mm^3 (*voxel* stands for "volume pixel," the unitary element of a three-dimensional image), can be acquired on a 1.5-tesla clinical scanner in less than 6 minutes.

The measurement of the relaxation time of the transverse component, which can be further split between the T2 and the T2* characteristic times, provides images that are influenced by the local inhomogeneity of the magnetic field, which in turn is increased by the local blood perfusion. In particular, T2*-weighted images are characterized by a contrast that highlights changes in vascular dynamics that accompany neural activity and are thus employed in functional mapping studies. The advent of a very fast technique for the acquisition of T2*-weighted images, called *echoplanar imaging* (EPI), allows the collection of an entire brain volume in 3–4 seconds and has been instrumental in the rapid development of functional MRI. The ultrarapid acquisition of EPI images and the nature of the detected T2* signal, which tends to become negligible when integrated over very small voxels, limit the resolution of standard EPI images, which typically have a voxel size of 3–4 mm per side. The use of particular technical and experimental arrangements has allowed, in special cases, the achievement of submillimetric precision, such as that required for the imaging of the columnar organization of visual cortex (Menon and Goodyear 1999). Table 10–2 includes the multiple applications of MR-based technologies in psychopharmacology.

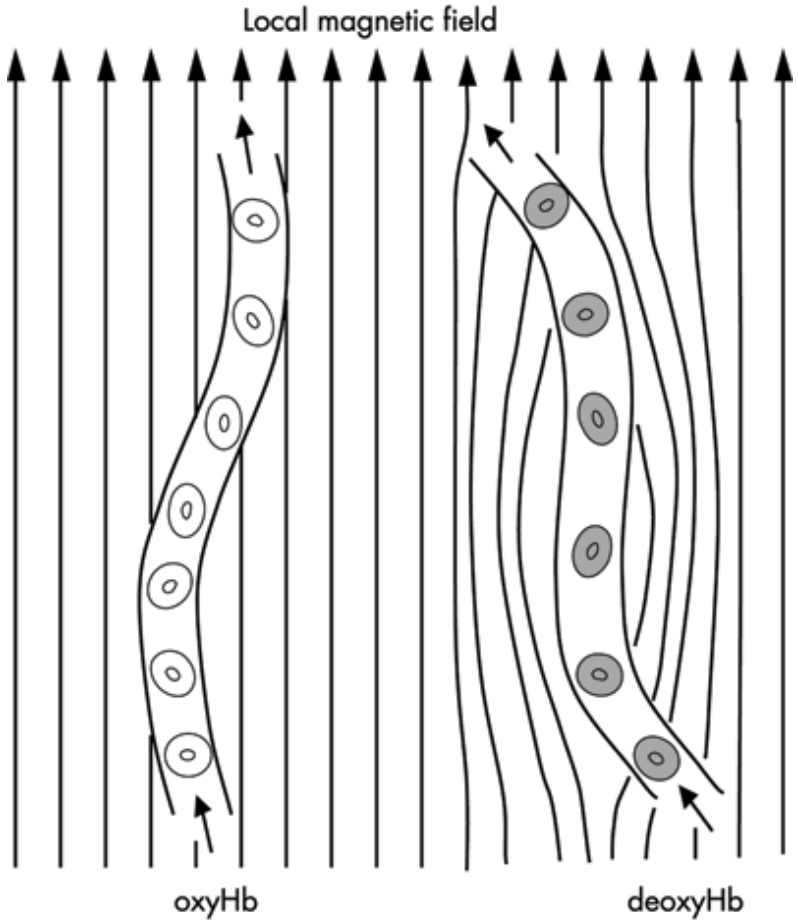
Functional MRI



Functional magnetic resonance imaging, or fMRI, refers to a variant of MRI that is sensitive to local changes in deoxyhemoglobin concentration. The increase in regional blood flow, as engendered by neural activation, overshoots the oxygen consumption. This results in an apparent *decrease* in deoxyhemoglobin. In the 1930s, Linus Pauling had observed that the amount of oxygen carried by hemoglobin is inversely proportional to the degree to which it perturbed a magnetic field. This property of differential paramagnetism was finally demonstrated in vivo in the late 1980s, and fMRI was born

(Ogawa et al. 1992; Thulborn et al. 1982).

The BOLD Signal in Functional MRI

Functional MRI exploits the fact that deoxyhemoglobin has paramagnetic properties and oxyhemoglobin does not. Deoxyhemoglobin disturbs the local magnetic environment, causing the surrounding protons to dephase even faster than they would otherwise (Figure 10–3).

FIGURE 10–3. Schematic diagram of the effect of hemoglobin (Hb) on the local magnetic field of brain tissue.

Only deoxyhemoglobin (deoxyHb) has paramagnetic properties and locally distorts the field, leading to faster spin dephasing.

Because neuronal activity leads to an overactive increase in blood flow, this actually decreases the amount of deoxyhemoglobin relative to oxyhemoglobin. Because less deoxyhemoglobin means less rapid spin dephasing, this increase in blood flow appears as an increase in MR signal. This is called the blood oxygenation level–dependent (BOLD) signal. In response to a regionally specific neuronal activation, the BOLD signal will usually increase by an amount on the order of 1% on a standard 1.5-tesla clinical scanner. The intensity of the signal is proportional to the strength of the main magnetic field—for example, it will double in the case of a 3-tesla scanner.

The temporal resolution of fMRI is determined both by the hemodynamic response and the physical constraints of the scanner magnetic fields. The hemodynamic response generally lags the neural activity by 3–5 seconds and may extend upward to 10–15 seconds (Figure 10–4). The rate at which the scanner can acquire images is influenced by the desired resolution. Generally, the more slices and the finer the resolution within each slice, the longer a whole-brain acquisition takes. While an individual slice can be acquired in as little as 60 milliseconds, whole-brain imaging usually requires about 2–3 seconds.

Whereas fMRI measurements are easy to perform, there are specific limitations with BOLD imaging.

1. The BOLD effect originates from venous vessels (capillaries, venules, and veins), so the signal is not exactly collocated either with the locus of neural activity or with the arterial supply. This spatial error may, however, be negligible for brain-mapping studies employing a standard spatial resolution (voxel size ~50 mm^3).
2. Bulk head motion and physiological pulsation (heart pulse, respiration) artifacts. For the motion, head movement should be restrained while maintaining a comfortable situation for the subject.
3. Susceptibility artifacts. The fact that BOLD detects local changes in magnetic susceptibility (due to the variation in deoxyhemoglobin concentration) renders it vulnerable to the large discontinuity that exists at the interfaces between bone/air and bone/liquid. In these regions, the steep variations in tissue density cause a distortion of the local magnetic field, resulting in both a spatial distortion of the image and a drop in the BOLD signal. This makes it difficult to detect the small changes associated with deoxyhemoglobin variations. The problematic regions are notably the orbitofrontal cortex and the inferior part of the temporal lobes, which unfortunately are

the locus of many interesting neuropsychological processes.

Functional MRI Experimental Designs

The particular characteristics of fMRI (i.e., its noninvasiveness and its spatiotemporal resolution) allow for its use in a variety of experimental designs. Two commonly employed schemas are block design and event-related design.

In a *block design* experiment, the experimental conditions alternate in blocks of some tens of seconds, each consisting of multiple repetitions of the same condition. In the subsequent statistical analysis, the scans acquired during the same block are pooled together to give an average effect. In an *event-related design,* each single experimental event/stimulus is modeled separately, which usually allows more latitude both in terms of the analysis (one can, for instance, separate the scan corresponding to a correct behavioral response from the scans corresponding to the subject's errors) and of the experiment itself (for instance, one can alternate between events of different types to avoid effects related to habituation). The analysis of such studies relies on the assumption of linearity in the BOLD response: if events of the same type are presented not too closely one to the other (the "linearity" seems to break down with an interstimulus interval of 1–2 seconds), then the resulting BOLD signal is simply the sum of the BOLD responses for the individual events.

Comparison of PET and Functional MRI

The advantages and disadvantages of PET versus fMRI are summarized in Table 10–3.

TABLE 10–3. Advantages and disadvantages of positron emission tomography (PET) versus functional magnetic resonance imaging (fMRI)

Advantages of PET versus fMRI
Quiet (good for acoustic stimulation); fMRI may have noise >90 dB
Less sensitive to movement artifact
Allows metabolic and receptor mapping
Allows imaging of brain regions that are typically difficult to image with fMRI because of the presence of a susceptibility artifact (orbitofrontal cortex, inferior temporal lobe) that causes both distortion and loss of signal
Allows the use of standard measurement devices (physiological, behavioral) inside the scanner (i.e., avoids the complication for the need of specially designed MRI-compatible hardware)
(In the MRI environment, the presence of a very strong static magnetic field commands the use of diamagnetic components; moreover, every electric device in the scanner room needs to be carefully shielded to prevent interference problems to and from the scanner. Scanning is not used in patients who have pacemakers or ferromagnetic metal parts in their bodies.)
Disadvantages of PET versus fMRI
Injection of a radioactive isotope precludes the use of PET for longitudinal studies in which the same subjects are scanned repeatedly over an extended period of time.
PET provides an integral measure (over time) of brain activity (for activation techniques), with a temporal resolution on the order of minutes because of the lifetime of the isotope. By comparison, fMRI has a temporal resolution on the order of seconds. This prevents the use of sophisticated, event-related designs with PET. Also, the number of images typically collected with PET on a single subject rarely exceeds a dozen, thereby limiting the statistical treatment in the analysis of the data.
Spatial resolution is more limited with PET than with fMRI.
Cyclotron must be located nearby.
PET is more expensive than fMRI (utilization costs per hour: fMRI, ~$500; PET, ~$2,000).

The acquisition procedure is time-consuming and requires more resources. (One scan typically lasts ~3 hours [fMRI typically lasts <1 hour]. In comparison, the MRI experimental setup is easier to perform and can be operated by just one person.)

Applications of Functional MRI in Psychopharmacological Research

At the time of writing this chapter, most of the applications of fMRI methods have been experimental—for example, helping investigators map areas of functional activation in response to cognitive and affective tasks. Similarly, several novel and innovative uses of imaging methods are seen in the literature, and the field has evolved considerably since the previous edition of this textbook. A few of these advances will be reviewed in this section and are also included in Table 10–2.

Neural activation in response to tasks

Measurement of neural activation patterns in response to specific tasks, using fMRI, has been particularly useful in elucidating the neural mechanisms contributing to the development of psychiatric disorders. Thus, specific tasks can be constructed that target specific emotional or cognitive behaviors that are altered in a given disorder. This research strategy allows delineation of neural pathways involved in the generation of specific symptoms and behaviors. A few examples of commonly used paradigms are discussed below.

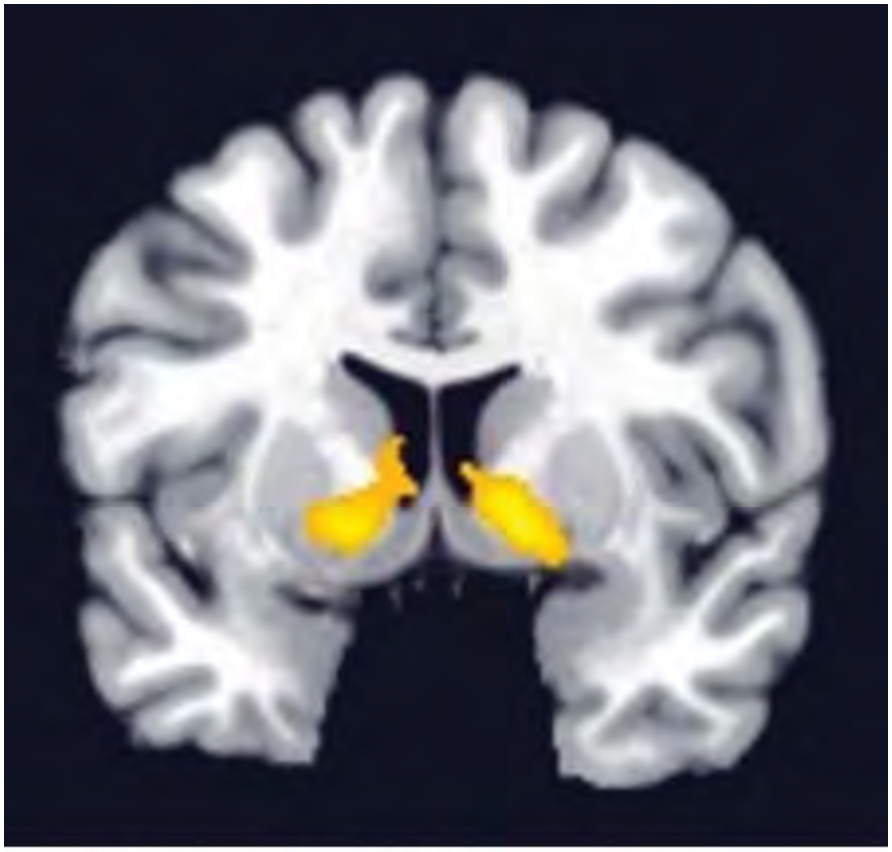
Mood/self-referential paradigms

As an example, a core feature of depression involves negative bias and anhedonia, suggesting specific alterations in neural pathways mediating salience, self-reference, and reward. Accordingly, several fMRI studies reported failed activation of dorsomedial prefrontal cortex (BA 10) in depressed patients in response to positive words or pictures (Le Bastard et al. 2003; Mitterschiffthaler et al. 2003). Interestingly, activation of this region is also seen in tasks requiring self-referencing in healthy subjects (Craik et al. 1999; Fossati et al. 2003). A depression-specific pattern has been described using an emotional "Go/No-Go task" that identified blunted responses in reward circuits in response to neutral words but exaggerated responses in self-referential areas of the rostral cingulate and medial frontal cortex in response to sad words (Elliott et al. 2002). Such sensitive tasks can plausibly be used as outcome measures in the evaluation of the efficacy of antidepressant treatments.

Facial expression–processing paradigms

Another task frequently used across a range of disorders involves the presentation of faces with different emotional expressions, such as angry, sad, fearful, happy, and neutral. Such faces can be either overtly presented or may be hidden behind a mask, depending on the study hypothesis. With overt presentation, subjects typically perform a behavioral task related to classifying some aspect of the faces. Application of such tasks in fMRI studies has produced a large amount of data regarding the neural basis of emotional processing in healthy subjects, reporting robust activation of the amygdala in response to emotional faces (Whalen et al. 1998). Of note, patients with depression, anxiety disorders, and PTSD exhibit increased amygdala responses to the presentation of fearful or angry faces (Rauch et al. 2000; Shin et al. 2005; Whalen et al. 2002). The paradigm has also proven useful to evaluate treatment effects of antidepressant drugs (Sheline et al. 2001), as well as temperamental or genetic contributions to emotional processing (Hariri et al. 2002; Stein et al. 2007). Similar strategies have identified antidepressant-induced changes with other tasks (Fu et al. 2007).

Cognitive "working memory" paradigms



Another common task used to identify neurocognitive changes is the so-called *n*-back task. The *n*-back task is a working memory task that reflects prefrontal cortical function. The *n*-back task has been used in fMRI studies to identify altered neural circuits in a variety of disorders, including schizophrenia and depression (Harvey et al. 2005; Meyer-Lindenberg and Weinberger 2006). The "*n*-back" working memory test (Owen et al. 2005) involves visual presentation of letter stimuli at previously chosen

intervals and epochs (e.g., 2-second interval for 30-second epochs). The baseline (control) condition is usually a 0-back condition in which subjects are required to press a button with the right index finger when the stimulus (e.g., the letter "x") appears. In the experimental condition (1-, 2-, or 3-back), subjects are required to press a button if the presented stimulus is the same as a stimulus presented *n* trials previously (*n* = 1, *n* = 2, or *n* = 3). The level of task difficulty and the condition are varied in a previously specified order throughout the scan time. Subject performance during scanning in regard to accuracy (number of target stimuli correctly identified) and response time (RT) is usually recorded. Interestingly, findings vary across disorders, suggesting differing impacts of underlying pathophysiology on networks mediating these behaviors. For example, increased prefrontal activity is seen in depressed patients relative to control subjects performing this task, an effect amplified by task difficulty (Harvey et al. 2005). On the other hand, several studies have reported that schizophrenic patients demonstrate deficits in activation of the prefrontal cortex during this task, thought to reflect alterations in dopamine functioning. Normalization of neural activation patterns by antipsychotic drugs is associated with response to treatment. The *n*-back task has also been useful in identifying genetic contributions to schizophrenia risk (Meyer-Lindenberg and Weinberger 2006). Bookheimer et al. (2000) used a verbal memory paradigm, in which patients memorized unrelated pairs of words during scanning, to study hippocampal activation in patients at risk of developing Alzheimer's disease. Not only did the carriers of the apolipoprotein epsilon 4 (*ApoE*-ε4)++ allele (higher risk of dementia) show greater hippocampal activation, but this baseline activation pattern predicted longitudinal cognitive decline.

Reward-processing paradigms

Reward-processing paradigms are commonly used in studying substance use and craving, but also in studying anhedonia in both depression and schizophrenia. In addiction studies, typically the patient, while lying in a scanner, is presented with multiple contexts associated with drug abuse, and activation of reward-processing circuitry is studied. Zink et al. (2006) used fMRI to study activation of the basal ganglia (a key component of reward circuitry) of healthy volunteers in response to salient stimuli with high motivational relevance. Figure 10–5 illustrates differential activation patterns in the ventral striatum in response to wins versus monetary losses during a gambling task, as measured with fMRI. The concept of "intertemporal discounting" is often used to describe choosing between discounted immediate reward to delayed reward at a rate that is much higher in value. Patients with impulse-control disorders such as pathological gambling show considerable variation in their tendency to use intertemporal discounting (Dixon et al. 2006). A recent study using fMRI reported that increased activation of paralimbic cortex was associated when choosing smaller/earlier rewards while fronto/parietal activation was seen when making the larger/later (opposite) type of choice (McClure et al. 2004). Studies such as these might help us develop brain activation–based biomarkers of complex disorders such as pathological gambling and substance abuse. A recent innovation in this field has been the development of "hyperscanning"—a method by which a person in an fMRI scanner at one location can interact with another person in another scanner using World Wide Web–based connectivity (Montague et al. 2002). Thus, the brain structures that are activated during social interactions could be studied using this technology.

Summary of neural activation paradigms

In conclusion, these examples illustrate the potential of fMRI activation studies in probing brain–behavior relationships in psychiatric disorders, owing to the flexibility of fMRI paradigm design as well as the large variety of standardized tasks and possibility to develop novel tasks.

Neuroimaging genomics

Despite the substantial advances in the pharmacotherapy of psychiatric disorders, response rates of patients remain unsatisfactory. For example, only 40%–70% of depressed patients adequately respond to 6 weeks of treatment with a single antidepressant drug. The factors that determine whether or not a patient will favorably respond to a specific drug are poorly understood, and there are no established strategies for clinicians to decide whether a patient might benefit from psychotherapy rather than pharmacotherapy (Binder and Holsboer 2006). Similarly, there is considerable individual variability in the response to antipsychotic drugs in patients with schizophrenia, which remains unexplained, and some but not other patients experience debilitating side effects (Reynolds et al. 2006). In concert with the rapid advances in the field of molecular genetics, there has been increasing recognition that genes influence individual differences in treatment response, as studied in the field of pharmacogenetics (see Chapter 3, "Genetics and Genomics"). Neuroimaging techniques have substantial potential to further the field of pharmacogenetics. There has been a surge of studies in recent years using neuroimaging to describe genetically determined differences in brain structure and function. Research strategies include neuroimaging studies in twin populations, unaffected individuals with high familial risk for a specific disorder (i.e., healthy siblings of patients), and groups of individuals with different variants of functional polymorphisms in genes involved in brain development or behavior (Hariri et al. 2006; Meyer-

Lindenberg and Weinberger 2006; Peper et al. 2007). Such studies not only advance our understanding of individual differences in cognitive and emotional behaviors, and the mechanisms involved in mental disorders, but also elucidate genetically determined variations in neural systems that are targeted by specific treatments. For example, one recent study found that the functional Val66Met polymorphism in the brain-derived neurotrophic factor (BDNF) gene moderates the association between depression and hippocampal volume loss. Carriers of the Met allele had smaller hippocampal volumes than subjects who were homozygous for the Val allele (Frodl et al. 2007). These findings suggest that the Met allele conveys increased risk for smaller hippocampi and susceptibility to depression. Because antidepressants stimulate neurogenesis in the hippocampus, carriers of the Met allele may be particularly responsive to antidepressant drugs.

In the area of schizophrenia research, it has been shown that a genetic variation (Val[108/158]Met) of catechol-*O*-methyltransferase (COMT), an important enzyme that degrades cortical dopamine at the synapse, is associated with deficits in working memory and prefrontal cortical activation in response to a working memory task. Specifically, carriers of the Val allele exhibit more deficits and less prefrontal cortical activation compared with subjects homozygous for the Met allele, likely reflecting low synaptic dopamine availability due to greater COMT activity, potentially increasing risk of developing schizophrenia (Meyer-Lindenberg and Weinberger 2006). Interestingly, the same polymorphism predicts effects of antipsychotic treatment on prefrontal cortical function in schizophrenic patients, as measured by fMRI, contributing to individual differences in treatment response (Bertolino et al. 2004). Based on such findings, COMT inhibitors are being investigated in the treatment of cognitive symptoms in schizophrenia.

Of course, in studying the effects of genes on neural responses to drugs, factors that interact with genes in shaping brain structure and function—for example, environmental factors across development—must be considered as well. In another example, it has been found that a functional polymorphism in the promoter region of the serotonin transporter gene—5-HTTLPR polymorphism (SCL6A4)—moderates the relationship between stress, including child maltreatment, and depression (Caspi et al. 2003; Kaufman et al. 2004; Kendler et al. 2005). Carriers of the short (S) allele had increased depression risk in relation to stress, whereas subjects homozygous for the long (L) allele were resilient even in the context of severe stress. Remarkably, S allele carriers demonstrate increased amygdala activation as well as decreased functional connectivity between amygdala and inhibitory prefrontal cortical regions in response to emotional stimuli, compared with L/L allele carriers (Hariri et al. 2002; Heinz et al. 2005; Pezawas et al. 2005). Of note, both the SCL6A4 polymorphism and developmental stress have been associated with treatment response to serotonergic drugs (Nemeroff et al. 2003; Reimold et al. 2007). Accordingly, neuroimaging is evolving as a valuable tool to evaluate gene–environment–drug interactions at the neural level. Such studies, taken together, have the potential to yield diagnostic markers to guide treatment decisions and identify targets for the prevention of manifest disorders in subjects at risk.

Default or resting-state functional imaging

Most studies reviewed so far have used challenges or probes that elicit neural activation and blood flow responses that could be captured by fMRI or PET scanners. Several authors have consistently found evidence for the existence of a "default" neural network that preferentially shows greater activity during restful or passive cognitive states (Buckner and Vincent 2007; Gusnard et al. 2001). High activity of these regions (posterior cingulate; inferior parietal and medial frontal cortices) during periods of wakeful rest and passive self-reflection have led some to hypothesize that this activity may "consolidate the past, stabilize brain ensembles, and prepare us for the future" (Buckner and Vincent 2007, p. 1066). Abnormalities in the functional connectivity of this network in psychiatric disorders such as schizophrenia (Bluhm et al. 2007), depression (Greicius et al. 2007), dementia (Rombouts et al. 2005), autism (Cherkassky et al. 2006), and multiple sclerosis (Lowe et al. 2002) have been reported. It is possible that further research into these default networks might yield key diagnostic or pathological

information about various psychiatric disorders.

Application of virtual reality–based techniques to functional imaging

Most of the recently available challenge tasks used in functional imaging are based on tasks or tests standardized for clinical testing. A major criticism of this approach has been that it might not be reflective of real-life situations. Consequently, some authors use virtual reality (VR)–based techniques to overcome this criticism. Ability to remember places and navigate through a VR-based city (similar to spatial memory testing in rodents) has been used in an fMRI environment to study activity of parietal and temporal cortices (Spiers and Maguire 2006).

Statistical modeling methods

A complex array of data is now available using functional and structural imaging methods in multiple states of activation within subjects and between groups, necessitating the use of elegant multivariate and multifactorial models (such as independent component analysis). A detailed description of these techniques is beyond the scope of this chapter and has been undertaken elsewhere (Pearlson and Calhoun 2007). Thus, using the related approach of structural equation modeling, it has been possible to compare functional activation changes across multiple scans and states: depressed subjects versus control subjects, treatment responders versus nonresponders, medication responders versus cognitive-behavioral therapy responders, and so forth (Chen et al. 2007). Use of such models has provided Chen and colleagues with the opportunity to identify and classify depression phenotypes at the level of neural systems, with future implications for evidence-based treatment selection.

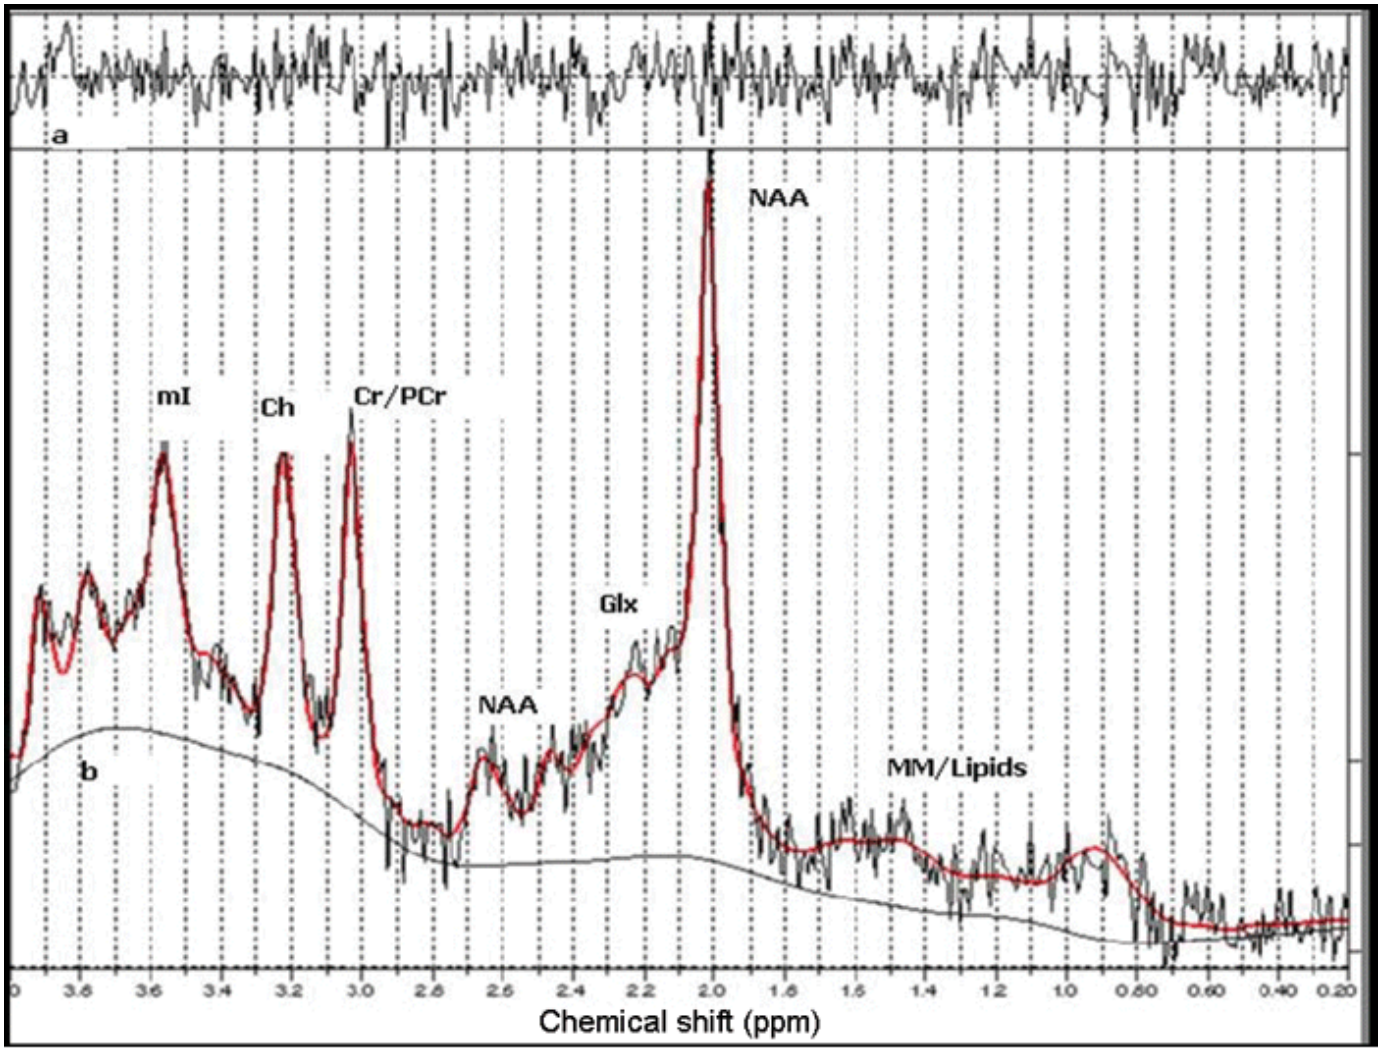
Structural MRI: Overview and Use in Psychopharmacological Research

As indicated in Table 10–2, MR technology has also provided important information on structural abnormalities in various psychiatric disorders. Use of these methods in the understanding of psychiatric disorders and their treatment will be addressed in the chapters on individual disorders. Only a general introduction will be provided here.

Volumetric Methods

Magnetic resonance–based volumetric methods involve estimating volumes of cerebral structures using MR images. They may be divided into two different types—automated (voxel-based morphometry [VBM]) and manual (region of interest [ROI]) methods. A detailed review of these methods is provided elsewhere (Pearlson and Calhoun 2007). Using volumetric studies of hippocampus in depression, Sheline et al. (2002) described a subtype of depression associated with hippocampal volume loss, memory impairment, and hippocampal loss of 5-HT_{2A} receptors. The alteration of cerebral structure by medications has been reported as well. G. J. Moore et al. (2000) reported that lithium administration led to a 3% increase in the volume of gray matter within a period of about 4 weeks. Psychiatric disorders are clinically heterogeneous entities and such structural MRI–based studies have helped us to characterize more specific pathological subtypes of depression. T2-weighted MRI studies have also been used to identify and rate subcortical hyperintensities, the increase of which is believed to result in late-life cerebrovascular disease and late-life depression (Alexopoulos et al. 1997; Kumar et al. 2002; Parsey and Krishnan 1997).

Diffusion Tensor Imaging and Tractography



Most of the previously described volumetric methods focus on gray matter structures as opposed to diffusion tensor imaging (DTI) and associated techniques that image white matter. DTI technologies image water diffusion to study the directionality and integrity of white matter connections between different locations of the brain (Kubicki et al. 2007). These studies advance the hypothesis that psychiatric disorders are characterized by altered connectivity ("disconnection syndromes"). These studies are beginning to help us understand the basis of cerebral organization and connectivity and how it might be affected in psychiatric disorders such as autism (Alexander et al. 2007), late-life depression

(Taylor et al. 2007), and schizophrenia (Nestor et al. 2007).

Magnetic Resonance Spectroscopy

MRS technology is based on the fact that MR acquisition involves receiving echoed RF waves of multiple cellular chemical constituents. The individual chemical and metabolite constituents could be measured by suppressing the resonance frequency of water molecules. A detailed exposition of the various types of MRS techniques is beyond the scope of this chapter, and the reader is referred to excellent reviews on the topic (Mason and Krystal 2006; C. M. Moore et al. 1999). Among the markers currently being researched are *N*-acetylaspartate (NAA), glutamate/glutamine (glx), myoinositol (mI), choline (Cho), glutathione, creatine, GABA, phosphomonoester (PME), and phosphodiester (PDE) (Lyoo and Renshaw 2002). An example of an MRS spectrum from a healthy control subject is provided in Figure 10–6. Using this approach, Frye et al. (2007)were able not only to demonstrate elevated glutamate/glutamine (glx) in anterior cingulate/medial prefrontal areas of patients with bipolar depression but also to document the reduction of glutamine among patients who showed clinical response to treatment with lamotrigine. Using proton MRS, C. M. Moore et al. (2007) measured multiple metabolites in the anterior cingulate cortex (ACC) of children with bipolar disorder and reported decreased glutamine concentrations in the presence of normal glutamate levels. Using another sample of adult patients, these same authors reported that anterior cingulate cortex glutamine levels were elevated rapidly following administration of the anticonvulsant topiramate (C. M. Moore et al. 2006). Using MRS technology, Sanacora et al. (2003) reported that cortical GABA concentrations increased following a course of electroconvulsive therapy and used this information to hypothesize that this increase in GABA might be associated with clinical recovery. Thus, MRS might provide very useful biomarkers of neural functioning and disease states among patients with psychiatric disorders.

ELECTROMAGNETIC MEASURES OF BRAIN ACTIVITY

The recording of the group electrical activity of neuronal assemblies is possible in human subjects with the techniques of EEG and MEG. In these techniques, electrical activity is recorded extracranially from the scalp of the individual in a noninvasive way (Bearden 2007). The appeal of these techniques is the extremely high temporal resolution (~msec), which allows one to follow the measurement of global patterns of neural activity in real time. Also, the electrical signal is directly related to the neural activity (in contrast to methods such as PET and fMRI, which rely on indirect assessment of neural activity through vascular effects), although the recorded electrical signals still represent an average over extended regions of the brain. This high temporal resolution makes them ideal candidates for studying synchrony phenomena (Tononi and Edelman 1998; Varela et al. 2001). Although considerable limitations and constraints exist in regard to spatial localization of activity across brain regions, these have mostly been overcome through technical and mathematical means. In spite of this, the spatial resolution, which depends also on the number of electrodes at one's disposal, remains quite poor in comparison with that

achievable with fMRI and is on the order of 1 centimeter. Also, the signals are quite weak, so the task has to be repeated a large number of times (tens or even hundreds).

The electromagnetic techniques record the scalp distribution of the field produced by the sum of mainly postsynaptic potentials of the neurons, each of which can be conceptualized as an electric dipole. EEG detects the electrical potential of the field, and MEG detects the magnetic component. The two techniques have very different technical requirements. EEG uses relatively simple equipment, basically a multielectrode helmet, an amplifying and filtering device, and a computer (Ebner et al. 1999). MEG, by contrast, employs cutting-edge technology (Ioannides 2006), because the detection of a magnetic field intensity as weak as the one produced by the brain (~20,000 billion times weaker than the intensity of the Earth's magnetic field) requires the use of superconducting coil units based on superconducting quantum interference device (SQUID) technology. These units need to be specially cooled to a temperature near absolute zero. To avoid the intrusion of electromagnetic interference from the environment, the recording takes place in a room that has been appropriately shielded.

A minimum of 32 scalp electrodes is needed to localize the sources of the recorded potential EEG, but high-density arrays of 128 or 256 electrodes are now common. MEG commonly employs arrays of 100–300 detectors. The intensity of the EEG or MEG response is typically very low, and it takes generally a large number of repetitions (~100) of the task/stimulus presentation (*trial*) to achieve a sufficient power. The time series from each of the recording units is then segmented according to the stimulus delivery sequence, and these temporally realigned segments are averaged together to obtain a waveform that represents the mean time course of the response to the trial for that recording location (*evoked potentials*). By combining these waveforms from all of the detectors, one can obtain a map of the surface field distribution at each time interval inside the trial window. Both EEG and MEG are essentially surface techniques: because the intensity of the electromagnetic field decreases rapidly with distance, the detection of neural signals is restricted to the sources closest to the detectors—that is, the neocortex. The activity of subcortical regions is very difficult to detect.

Use of Electroencephalography and Magnetoencephalography in Psychopharmacology

While these techniques carry considerable potential, their use in psychopharmacology remains elusive. The use of EEG and related technology of evoked potentials has helped contribute considerably to our understanding of the pathophysiology of schizophrenia (Ford and Mathalon 2005; Turetsky et al. 1998). Tucker et al. (2003) used dense-array EEG to study frontolimbic responsiveness in patients with moderate depression. A potential for the use of EEG technology used in conjunction with fMRI in study of analgesia and pain management has been recommended by some authors (Wise and Tracey 2006). Pizzagalli et al. (2003) combined PET and EEG technologies using a source localization technique to identify disruption of frontocingulate connectivity among patients with depression. Studies such as these provide critical information that can complement and enhance our understanding of functional imaging approaches.

CONCLUSION

Contemporary brain imaging methods provide a variety of strategies to probe structural, functional, and chemical abnormalities in specific neural circuits relevant to psychiatric disease. Such studies are having a considerable impact on our conceptualization of these disorders, with potential impacts on diagnosis (Mayberg 2003a), clinical management (monitoring occupancy, or PIB changes with treatment [Klunk et al. 2004]), and novel treatment development (Mayberg et al. 2005). Brain imaging in psychopharmacology can be categorized both by the scanning technology (e.g., MRI, PET, or EEG) and by its purpose (e.g., activation, resting state, behavioral, biochemical, or receptor mapping). Receptor-mapping studies have clearly added to our ability to understand mechanisms of action of psychopharmacological agents and their side-effect profiles. Activation studies, which indirectly measure neuronal activity vis-à-vis changes in cerebral blood flow, have become widely used with fMRI technology, providing new insights into behaviorally specific subcircuits. Structural MRI studies have

also begun to yield considerable data enabling a better understanding of how the disease processes are regionally localized, where to target for functional imaging, and where to obtain specimens for postmortem histopathological analysis. Multimodal imaging through the combination of fMRI, PET, structural MRI, MRS, and electromagnetic measurements (EEG, MEG) offers the promise of identifying both neuronal and chemical changes related to brain function.

Chapter 11. Statistics, Placebo Response, and Clinical Trial Design in Psychopharmacology

STATISTICS, PLACEBO RESPONSE, AND CLINICAL TRIAL DESIGN IN PSYCHOPHARMACOLOGY: INTRODUCTION

Drug development is a highly complex process that involves multiple steps of preclinical and clinical pharmacological refinement and testing. Preclinical studies include assessing drug bioavailability, metabolism, and toxicity; effects on known biological targets (e.g., receptor binding); and performance in various animal models of pathology. After sufficient data are obtained in animal studies, drug testing in humans can begin. In the United States, human clinical trials are divided into four phases. Phase I involves testing multiple doses of a drug for bioavailability, pharmacokinetics, and side effects. Phase II studies are dose-finding studies in patients with a given disorder. They can be open-label or double-blind trials. Phase III generally includes pivotal double-blind trials for demonstrating efficacy and safety/tolerability. Phase IV trials, which take place after a drug has received U.S. Food and Drug Administration (FDA) approval and is on the market, are conducted to help clarify potential uses of the drug.

Generally, efficacy is established via a randomized, controlled trial (RCT) in which a test drug is compared with a so-called placebo and/or an active compound. An RCT is an experiment designed to establish the efficacy of a treatment by comparing the responses in two or more groups of patients sampled from a relevant clinical population, with one group randomly assigned to receive the treatment of interest and a second group randomly assigned to receive a control treatment, in which all subjects are enrolled, treated, and uniformly followed over the same time period (Meinert 1986). In contrast, experiments that are performed under any of the following circumstances are not RCTs:

1. Using human tissues or animals
2. For purposes other than establishing efficacy of a treatment
3. Comparing groups of patients who were selected rather than randomly assigned to receive a given treatment (observational, or *quasi-randomized,* clinical trials)
4. Assessing response to a treatment in absence of a control group (e.g., pre–post study designs)
5. Comparing a group of patients given a treatment versus another group given another treatment observed at different times or places (e.g., historical control subjects)

Although the basic premise underlying the RCT has remained the same over the past half century, RCTs today differ from RCTs of the 1950s. Advances have occurred not only in statistical methodology but also in research methods; studies are now better designed to promote the replicability of the results and thus to protect the validity of inferences drawn from RCTs and applied to patient populations. The basic premise underlying the RCT defines the "causal effect of treatment (T) on an individual patient" as a comparison between a patient's response to T with what the outcome in that same patient would have been if that patient had not been given T (Rubin 1974, 2004). The condition proposed to represent what would have happened if that patient had not been given T is generally called the *control* or *comparison* group (hereafter referred to as *C*).

Unfortunately, there is no way to assess response to any treatment for an individual patient under two

conditions, T and C, simultaneously. If a treatment were given to the same patient at different times, the condition of the patient might change between the first and second time (*secular trends*), or the response to treatment the first time may influence the response to treatment the second time (*carryover effects*). Consequently, how much of any difference seen between the two responses is attributable to T per se and how much is attributable to other, extraneous influences cannot be ascertained. Thus, the causal effect of T in an individual patient cannot be assessed. However, what cannot be done with an individual patient can be done with a clinical population. Patients in a representative sample from the clinical population of interest can be randomly assigned to receive either T or C. Under optimal conditions in a rigorously controlled study, the average responses in the two groups are estimates of what the average responses to receiving T and to not receiving T would be within the entire population, and the comparison between them is an estimate of the average causal effect of T on the population sampled.

In designing an optimal RCT the following issues need to be considered, all of which we address at least briefly in this chapter:

- Specific indications and populations to be studied
- Drug formulation and doses to be used
- Route and time of administration
- Instruments to be used as outcome measures
- What the comparison groups should be
- Power analysis and statistical analysis tools

The question of what the comparison groups should be is especially important. The issue of whether to compare the treatment with a placebo or an active control has become a contentious social and ethical issue as well as a scientific issue, particularly regarding psychiatric patients with severe disorders such as schizophrenia, and we focus strongly on that issue in this chapter.

INDICATIONS

An indication for a drug is really an administrative approval by a regulatory authority (in the United States, the FDA) for a company to market and sell a product for a specific clinical need. To establish efficacy in treating psychiatric illness, the FDA has generally required statistically significant results in trials. Generally the requirement has been for more than one statistically significant study outcome, although there have been exceptions to this rule. Historically, indications have revolved around syndromes (e.g., treatment of major depression or schizophrenia). More recently, the FDA has shown greater flexibility with approvals for drugs to treat symptom dimensions—e.g., agitation—that transcend underlying syndromes.

The population to be sampled is a matter of some importance because one cannot generalize the result beyond the population the sample actually represents. Thus, for example, a study that samples alcoholic patients but excludes those with comorbidities will generate a sample that represents a small fraction of the population with that disorder (Humphreys and Weisner 2000; Humphreys et al. 2005). Whether or not some advantage is found for T over C in such a nonrepresentative subpopulation gives little insight as to whether that same advantage pertains in the majority of people with the disorder.

The choice of population to be sampled is also crucial to differentiating efficacy from effectiveness. *Efficacy* refers to the extent to which T produces a beneficial result under ideal conditions; *effectiveness* refers to the extent to which T produces a beneficial result when used as it would be in actual clinical practice (Hoagwood et al. 1995). Both issues are best addressed with RCTs. One crucial difference between RCTs geared toward establishing efficacy and those geared toward establishing effectiveness is the population that the RCT researchers choose to sample. RCTs directed more toward establishing efficacy usually set very narrow inclusion/exclusion criteria, focusing on the subpopulation of patients with the disorder who are most likely to comply and to respond well. In

contrast, RCTs directed more toward effectiveness try to use patients who are representative of all those with the disorder who might benefit from that treatment for their disorder. The primary reason for exclusion from effectiveness RCTs is usually that there is some reason to believe that either T or C is contraindicated (e.g., pregnancy excludes women in many drug studies) or the patient is unwilling to sign an informed consent form. Because the sample in an efficacy study is chosen to be more compliant and responsive, and is typically more homogeneous than that in an effectiveness study, sample sizes are likely to be much smaller than those in an effectiveness study, and effect sizes much larger.

The earliest studies of a particular drug are likely to be efficacy studies in order to establish that the drug works at least under optimal conditions. For pivotal studies, hypotheses are stated a priori. Generally, these take the form that a tested treatment will be superior to a comparator in reducing a given set of symptoms over a specific duration of treatment. A statistical analysis plan is developed to test the a priori hypothesis. The most influential studies on clinical practice, however, are likely to be effectiveness studies, for they inform clinicians about which treatments might benefit the patients they are likely to see.

Clinical development of psychiatric agents is such that approval for indications are usually for adults (i.e., over the age of 18 years) and for both sexes. Specific additional approvals can be sought for children and the elderly. Obviously, in disorders that occur primarily in childhood (e.g., attention-deficit/hyperactivity disorder), studies may begin with youths.

Establishing Diagnoses

Establishing an accurate diagnosis is generally done according to criteria from an established classification system—e.g., the *Diagnostic and Statistical Manual of Mental Disorders,* 4th Edition, Text Revision (DSM-IV-TR; American Psychiatric Association 2000). Criteria can be checked off using an unstructured clinical interview or by using a structured instrument—the Scheduled Clinical Interview for DSM-IV (SCID). The latter is more time-consuming but can offer greater information on diagnoses, particularly in cases of psychiatric comorbidity. Obviously, the use of the SCID requires training and assessment for interrater reliability, as well as monitoring over the course of the trial to prevent "slippage" of diagnostic standards.

Rating Instruments

Because in psychiatry we do not yet have reliable biological measures (e.g., a serum lipid panel) to assess efficacy, we rely on objective rating instruments applied by an observer or on self-reporting. Before being used in a study on drug efficacy, the instruments need to be assessed for both validity and clinical relevancy, and reliability and consistency must be established in the population to be sampled and in the hands of the RCT research staff. This is particularly true in multisite RCTs, where special efforts are necessary to ensure that the primary outcome measure is the same across the sites. Lack of reliability, lack of consistency between raters, or lack of consistency across sites in a multisite RCT is likely to lead to a failed RCT, one unable to establish statistically significant differences between T and C.

An RCT should have only one primary outcome being measured—or very few—and all the decisions in study design, measurement, and analysis are directed toward generating valid and powerful tests for that primary outcome. Other outcomes can be assessed in the study, as long as they do not compromise assessment of the primary outcome and do not impose undue burden on patients and research staff that would lead to dropouts and diminished reliability of measures. Outcome assessments that amplify or elucidate the primary outcome results are generally listed as secondary outcomes. Finally, it is necessary at baseline to collect enough information to well characterize the sample, both sociodemographically and clinically, to check the adequacy of randomization in producing two groups assigned to T and C that are comparable at baseline.

Such baseline data also are valuable in post hoc exploratory analyses to assess the possibility of moderators of treatment response (identification of subpopulations that have different effect sizes) (Kraemer 2008; Kraemer et al. 2006, 2008).

During treatment, there may be repeated assessments of the primary and secondary outcomes, which can be used in analysis of results using methods such as hierarchical modeling that generally deal much more effectively with dropouts and missing data; such methods usually increase the power to detect T versus C effects without requiring an increase in the sample size. Events or changes that happen during the treatment may also be used in post hoc analysis to identify mediators (possible mechanisms) that indicate how and why T works better than C (or does not), which can then lead to improved treatments for evaluation in future studies.

Such descriptive statistics or the results of post hoc analyses lead not to conclusions but rather to hypotheses that would be tested in future RCTs, but they are essential to the advancement of treatments.

In seeking approval for an indication, observer-rated instruments are generally preferred over self-reports. However, some studies employ self-report measures to test secondary hypotheses. Over time, a commonly used measure may be supplanted by another that is believed to more accurately reflect specific symptoms to be studied. Some of these scales are quite different from each other. For example, the Montgomery-Åsberg Depression Rating Scale (MADRS) has been used in antidepressant trials as an alternative to the Hamilton Rating Scale for Depression (Ham-D) because the former focuses less on anxiety symptoms and more on core depression. Other scales may be expansions on existing ones, adding items to focus on specific symptoms in a particular disorder. An example is the use of the Positive and Negative Syndrome Scale (PANSS) for schizophrenia. The scale is an expansion of the classic Brief Psychiatric Rating Scale (BPRS). Detailed descriptions of rating scales can be found in a source textbook edited by Rush et al. (2008).

Application of a validated and reliable instrument still requires that raters be trained and that a high degree of agreement (interrater reliability) be found among raters, both cross-sectionally and over time. This generally requires formally training raters and then testing multiple raters on patient vignettes to establish interrater reliability. In many cases, patient interviews might be videotaped and randomly selected videotapes submitted to independent experts to assess the reliability and consistency of ratings. Again, this is particularly important with multisite RCTs.

Symptom Severity Criteria

Historically, minimal levels of symptom severity on rating scales have been incorporated into study inclusion criteria. These criteria are aimed at ensuring that patients have at least a minimum level of symptom severity at baseline to allow for assessing relative effects of a therapy. Issues arise in implementing these inclusion criteria, particularly a possible inflation of rating scale scores to ensure inclusion. This can become an important issue in studies with relatively few patients. To counter possible severity rating inflation, several tactics have been employed, including audio- or videotaping of entry interviews with subsequent quality review; use of self-reporting or an interview rating done outside the study for inclusion; not specifying minimal entry symptom severity criteria to the investigator; and ensuring that there is funding to cover the costs of screening failures.

Whenever entry criteria specify a threshold inclusion, there is the risk of regression to the mean in both the T and C groups. Although regression to the mean (Campbell and Kenny 1999) in an RCT does not bias the comparison of T versus C effects, the use of an entry criterion may focus attention on the very subgroup in which T is least, rather than most, effective, which might lead to a failed RCT. The alternative is to include all those in whom clinicians might use T rather than C (effectiveness criteria) and then use post hoc moderator analyses to determine whether those within a certain range of baseline severity are likely to have the greatest effect sizes.

Trial Duration, Drug Dosage, and Route of Administration

Protocol development requires specifying the duration of the trial a priori. The optimal duration varies across disorders. For example, for acute treatment of major depression, commonly 6–8 weeks of active treatment are employed; for mania, 3 weeks' duration is common. The shorter trial length for acute mania is used for convenience to allow sufficient time to assess a novel therapy without an unduly long duration of placebo treatment that would discourage enrollment.

Route of administration and specific dosage regimens are determined for each agent and vary according to the agent's physical properties (e.g., half-life, absorption) as well as the indication. (These are frequently determined in Phase II trials.) Drugs that can be prescribed once per day are obviously more convenient to administer than are agents that require multiple daily dosing, so manufacturers strive for once-daily dosing.

STATISTICAL ISSUES IN PLANNING

Sampling, Randomization, and Blinding

The basics strategies of the RCT methodology are simple: appropriate patient sampling, choice of control group, randomization, and blinded assessment. However, each basic requirement can be satisfied in a myriad of ways, only some of which are valid in a particular RCT. What is ideal in one RCT may be either precluded or the worst choice in another. However, if all is done appropriately in the particular context of the RCT, nonrandom differences in response between the T and C groups reported as a *statistically significant* effect of T versus C are attributable to the treatment (thus the effect of T) rather than to biases in sampling, group assignment, measurement, or analysis.

Given that randomization is done to generate two random samples from the *same* population, any postrandomization removal of patients from the sample has the potential of biasing those samples relative to each other, and relative to the parent population. Consequently, RCT methodology also requires analysis of results *by intention to treat.* Every patient randomly assigned to a group (i.e., with the intention to treat) must be considered in the analysis comparing responses in the T and the C groups. In absence of an intention-to-treat analysis, when there is any postrandomization removal of patients from the randomized sample, the trial is no longer an RCT, because it is not based on comparison with randomized treatment and control groups. It is in this context that repeated measures of the primary outcome over the duration of treatment are particularly useful, for partial response data can be used to impute values for missing data or postdropout data, thus minimizing the associated loss of power.

To ensure that response is measured exactly the same in T and C groups, either objective outcome measures should be used or the assessor should be unaware of the treatment group to which a subject was assigned (i.e., "blinded").

Statistical Significance and Clinical Significance (Effect Sizes)

It must be emphasized that a *statistically significant* effect of T, with $P < 0.05$, merely means that the data satisfy minimal requirements to show a nonrandom difference between T and C. If $P < 0.01$ or $P < 0.001$, etc., the data satisfy more than minimal requirements, but the conclusion remains only that there is a nonrandom difference between T and C. Thus, a statistically significant effect of T may or may not be large, important, or of any clinical significance.

To show that a statistically significant effect of T is of clinical significance as well, descriptive statistics and an effect size should be reported (as required by the Consolidated Standards of Reporting Trials [CONSORT] guidelines) (Altman et al. 2001; Rennie 1996). For example, how likely is a patient given T to have a response that is clinically preferable to the response of a patient given C (an effect size called *area under the curve* [AUC]) (Acion et al. 2006; Grissom 1994; Kraemer and

Kupfer 2006)? Or how many patients would have to be given T to have one more "success" than if they had all been given C (another effect size, called *number needed to treat*) (Altman et al. 2001; Grissom and Kim 2005; Kraemer and Kupfer 2006; Wen et al. 2005)?

By the time there is rationale and justification to propose an RCT to compare T versus C, it is very unlikely that the null hypothesis of randomness is exactly true (Jones and Tukey 2000; Meehl 1967). In any case, with the best possible RCT, there is still a 5% chance of a false-positive result even if the null hypothesis of randomness is exactly true. Thus, given a large enough sample size, and/or given enough RCTs comparing T versus C, every T could eventually be declared statistically significantly better than any C. Accordingly, in recent years the costs of exclusive emphasis on statistical significance have been recognized. There is now growing emphasis on reporting effect sizes that are clinically interpretable (Altman et al. 2001; Grissom and Kim 2005; Kraemer and Kupfer 2006).

CHOICE OF CONTROL GROUP

Among all the myriad sampling, design, and analysis questions that need to be addressed in proposing an RCT, the most contentious continues to be: What is C?; that is, what is the appropriate control group (or set of groups) in a particular RCT? More specifically, when is a placebo control group the appropriate choice? If not a placebo control group, then what? These are the questions to which we here turn our attention, questions that continue to be the focus of much disagreement and argument, even among experts in RCT methodology or application, ranging from many who propose that a placebo control group *always* be included in an RCT to some others who propose that it *never* be included.

In what follows we consider a variety of options for a control group, beginning with a few options that are, by strict definition, not RCTs. It is important to realize why these options are considered unacceptable, for those are the same considerations that apply when considering other possible choices for control groups, particularly that of a placebo control group. Then we discuss the choice of the placebo control group in some detail, ending with consideration of the *treatment-as-usual* (TAU) control group and the *standard-of-treatment* control group, the most common alternatives to the placebo control group.

Each Patient as His or Her Own Control (Pre–Post Study Design)

The very simplest, but unacceptable, proposal is to compare patients' conditions prior to and after treatment with T, with no control group and no randomization (hence not an RCT). Any change in condition beyond that consistent with random variation is taken to indicate a treatment effect. Researchers unable to detect a statistically significant difference between T and C groups in an RCT often report such pre–post comparisons as indicating an equally beneficial "effect" in the groups, a misinterpretation of statistical significance.

With any treatment, even a completely inert placebo, it is very unusual, given a large enough sample size, to *not* see a statistically significant change in patients' conditions pre- and posttreatment. Such a change is attributable not to the effect of that treatment but rather to artifacts of various kinds that a control group is meant to "control" for, as discussed below:

1. The first artifact is statistical regression to the mean (Blomqvist 1986; Campbell and Kenny 1999; Davis 1976; Senn 1997; Stigler 1997). Patients are selected for participation because they have symptoms of a disorder severe enough to require treatment (especially if there is an explicit cutoff point on severity required for inclusion), and frequently the outcome measures evaluate severity of the same symptoms. However, assessment of symptom severity at entry is never completely reliable. With error of measurement due to day-to-day inconsistencies in patients' conditions, coupled with assessor bias and random error, patients with a false-positive assessment at entry are included in the study, but patients in the population with a false-negative assessment at entry are excluded. In absence of any effect of treatment on their

clinical condition, those patients with a false-positive assessment at study entry are likely to later have their symptoms be assessed as closer to their true level, creating the false appearance of overall improvement.

2. Second are expectation effects. Both patients and assessors hope and expect to see improvement after onset of treatment. As Yogi Berra is reported to have said: "If I hadn't believed it, I wouldn't have seen it!" The power of suggestion is very strong, particularly in the process of recruitment into an RCT. The informed consent process, as well as patients' awareness of physicians' sworn obligation to do no harm, combined with the patients' pain, needs, and hopes, tends to bolster expectation effects.
3. Third are possible secular trends both in the condition of the patients and in the measurements of response. In some cases, patients with a disorder, receiving only the close and caring attention given in both T and C groups, spontaneously improve. At the same time, how assessors view a patient's response can change over time. With blinding, these effects are the same for patients in the T and C groups.

The cumulative effect of these and other artifactual influences constitutes the *placebo response,* which is experienced by those in *both* the T and C groups, whatever C might be, but which is expressed in its pure form in a placebo control group. With randomization to the T and C groups and blinded assessment, the effect attributable to T is the differential response of the T and C groups, not the responses to T or to C separately. Thus, pre–post comparisons within a single treatment group may be of some clinical interest, and worth reporting, but are not adequate to establish the efficacy or effectiveness of any treatment.

Historical Control Groups

The pre–post treatment comparison as an indicator of treatment effect does away with the RCT requirements of a control group, of randomization, and of evaluator blinding. Another unacceptable alternative acknowledges the necessity of a control group but tries to do away with randomization and blinding: the *historical control group.*

Here, as in pre–post studies, all patients recruited into the study receive T. However, information is obtained from clinical records and from past RCTs and other research studies on what happened to patients who received C—a historical rather than a concurrent control group. The treatment effect is then inferred from comparisons of the T group with the historical control group.

It has long been known that when one recruits patients from different sources (e.g., different sites, different recruitment pools, or at different times), what is seen, even in response to the same treatment in samples satisfying the same inclusion/exclusion criteria, is different. It is usually hoped that the effects of T versus C within each source are much the same (generalizability) in patients recruited from different sources, but the responses within the individual T and C groups are expected to differ sharply in patients recruited from one source versus another. With a historical control group, any difference seen may be due wholly or in part to site/time/context effects rather than being due to the effect of T versus C, and the effect size that is estimated and tested is not valid for establishing the efficacy or effectiveness of a treatment.

Withhold Treatment: Waiting List Control Groups

Yet another proposal, one consistent with RCT methodology but still questionable, is to randomly assign patients either to the T group or to a *waiting list control group.* Those in the waiting list control group are asked to refrain from seeking treatment for their disorder for the duration of the RCT, at the end of which they are given T if they then wish to receive it.

There is an ethical problem here. Patients being recruited into an RCT suffer from some disorder for which they seek help. It is difficult in many cases for clinical researchers to maintain *clinical equipoise* —defined as "a state of genuine uncertainty on the part of the clinical investigator regarding the comparative therapeutic merits of each arm in a trial" (Freedman 1987)—when the choices are between using a treatment that has a rationale, and for which there is justification for a belief that it

might be helpful, and denying treatment for the duration of the study. Clinical equipoise is not solely an issue related to ethics. Lack of clinical equipoise often has repercussions for the scientific validity of the RCT, because when researchers are sure that T is better than the selected C, it is difficult to ensure the scientific objectivity necessary to the design, conduct, and analysis of the trial in order to produce a balanced and fair comparison of T versus C.

Clearly, if the disorder that the patients have is not serious, disabling, or painful; if it is unlikely to worsen with a delay in treatment; and particularly if no treatments are available for the condition outside the RCT that the patients would have had access to had they not been in the RCT, there is no convincing ethical argument for withholding treatment. However, it is not the ethical considerations but rather practical considerations that make the choice of withholding treatment untenable.

When patients seeking help for a disorder are able to obtain treatment from clinicians in their community, patients are less likely to volunteer for an RCT in which they take a chance of having such help withheld. Thus, the sample that is recruited into an RCT with a waiting list control group is likely to be nonrepresentative of the population with the disorder, often missing adequate representation of those most seriously affected by the disorder and those most anxious to be relieved of the effects of the disorder.

Moreover, after randomization, patients in the control group are more likely to drop out to seek outside help, introducing bias to the RCT and loss of power. Indeed, in many cases, clinicians observing patients in the waiting list control group often relent and transfer patients from the control group to treatment group prior to the end of the RCT, because of clinical ethical concerns.

Technically, this is a valid RCT proposal, because there is a C (in this case, temporary withholding of treatment) and randomization to T and C groups. However, in waiting list–controlled RCTs, it is very difficult to blind assessment of the outcomes. Patients are often very aware that they are receiving no treatment for their disorder and such awareness can color all measures of response. Consequently, the problems of sample bias, measurement bias, missing data, dropouts, loss of power, and bias in resulting effect sizes militate against choosing a waiting list control group in most cases.

Placebo Control Groups

A *placebo* is defined as an inert medication or procedure, one that is selected specifically because it cannot affect the underlying process of the disorder: a saline injection, a sugar pill. When a patient given placebo appears to respond, such a response is often mistakenly labeled a *placebo effect.* However, since this response cannot be attributed to the placebo, the more appropriate label is *placebo response.* As noted above, the placebo response is experienced both by those receiving T and those receiving C, but it is experienced in its pure form only by those in a placebo control group (see "Each Patient as His or Her Own Control [Pre–Post Study Design]").

Because of the artifacts associated with pre–post study designs (regression to the mean, expectation effects, secular trends in the clinical condition of the patient or in the measurement process, etc.), it is very common for patients randomly assigned to placebo treatment to appear to respond favorably. In fact, it is reasonable to expect that given a large enough sample size, one will always find a statistically significant placebo response.

There has long been discussion of how one might 1) understand the placebo response and 2) reduce the placebo response in RCTs to make it easier to detect the efficacy or effectiveness of treatment versus placebo. That portion of placebo response related to artifacts, however, is already well understood. They are controlled in well-designed RCTs to the extent that is possible, by use of reliable measures and consistent application of measurement protocols over the course of the RCT.

Clinically, the most interesting aspect of placebo response is the expectation effect in both patients and assessors of response. Why would we want to reduce such expectation effects? Such expectations

have a great deal to do with compliance and cooperation of patients during RCTs, as well as with their potential response to treatment. It would certainly be worthwhile to understand on whom one might expect strong expectation effects, how and why they exist, and exactly how they influence clinical response to treatment. But the goal would be to consider how to *increase* expectation effects to maximize the efficacy or effectiveness of any treatment, rather than to *reduce* them.

Like the waiting list control group, the placebo control group amounts to a withholding of treatment for the duration of the study. However, having a placebo control group repairs many, though not all, of the technical problems associated with a waiting list control group. One clear advantage is that use of a placebo control group facilitates blinding of outcome measurement. Thus, the problem of measurement bias expected in waiting list–controlled RCTs can be obviated in a placebo-controlled trial.

In the past, many patients did not actually understand what a placebo was, and when U.S. drug studies are conducted in Third World countries, this problem is still of concern. With the growing sophistication of medical consumers and medical advocates, however, and with the increasing scrutiny of how the placebo group is described in informed consent forms, this is less of a problem today. As is the case for use of waiting list control groups, patients with the greatest impairment from their disorder—who are most anxious to get relief, most in need of effective treatment, and most likely to cooperate and comply with treatment—are less likely to be willing to agree to randomization in a placebo-controlled trial. Moreover, their primary care physicians often have the same reaction and are reluctant to recommend participation in an RCT for those most in need of treatment. Thus, placebo-controlled trials run a strong risk of having a nonrepresentative sample from the relevant clinical population. Accordingly, the CONSORT guidelines for reporting the results of an RCT (Altman et al. 2001) ask that researchers provide a patient flowchart that includes how many patients were eligible for the RCT and how many refused participation. This information sheds light on the possible sample bias in any RCT but particularly in a placebo-controlled one.

Moreover, the problems that waiting list–controlled RCTs have with dropouts can be exacerbated (Kemmler et al. 2005) by substituting a placebo control group. Now patients in *both* the active treatment and placebo control groups are equally aware that they might be receiving a placebo. Patients in either group who do not experience the relief from their disorder that they hope for are likely to suspect that they are in the placebo control group, and thus are likely to drop out of the RCT. Again, their physicians, observing no amelioration of symptoms, may add to the problem by recommending dropping out and initiation of what they would consider effective treatment. Once again, such concerns are reflected in the CONSORT guidelines (Altman et al. 2001) with the requirement that researchers report the number of patients randomly assigned to each group (the intention-to-treat samples) and the number that drop out in each group, with reasons for such dropouts. This information is intended to help assess the possible biases that might result from such dropouts.

The RCT requirement that all randomly assigned patients be considered in assessing the treatment effect (an intention-to-treat analysis) in the face of any appreciable dropout is difficult to comply with. Although imputation methods, both simple and complex, are often used, there is no imputation procedure that completely corrects for the impact of dropouts or missing data on an RCT that are directly related to the experiences of patients with the treatment that they were assigned to receive. The fact that a placebo control often increases the risk for dropouts and missing data is thus an important consideration.

Although missing data and dropouts remain major issues in considering the use of placebo control groups, the major source of contention arises not from the theory of RCTs, or from the implementation problems of RCTs, but rather from the ethics of proposing a placebo-controlled RCT in the first place and from the clinical value of the results of a placebo-controlled RCT. To understand these arguments,

let us consider a few specific contexts in which placebo control groups might be considered.

When Is Use of a Placebo Control Group Unarguable?

When Usual Treatment Is No Treatment

Little or no argument about the choice of placebo as the control group in an RCT occurs when the usual treatment by clinicians in the community is no treatment at all. Then, using a placebo in the control group mimics clinicians' recommendations exactly in providing no treatment that can influence the disorder.

In such cases, patients may be better off volunteering for participation in an RCT, where they have at least a chance of being assigned to receive an effective treatment. Patients might actually respond better to a placebo in an RCT than to absence of treatment in the community because of one of the artifactual responses that the control group controls for. For example, the attention, care, and scrutiny provided to patients in an RCT are usually far beyond those provided in usual clinical practice, and that may benefit patients. For all these reasons, when usual care in the community is no treatment, patients have strong inducement to volunteer to participate in a placebo-controlled RCT.

Moreover, in this situation patients have little inducement to drop out of the RCT, for nothing is available as an alternative in the community that can be better than what is offered in the placebo control group, and what is offered in the T group may improve their condition. Thus, when usual treatment in the community is no treatment, placebo control groups are the only choice, and an excellent choice at that.

In Seeking FDA Approval

Even when there are treatments thought to be effective in the community for a disorder (often other drug companies' products), drug companies generally prefer placebo control groups in studies directed to the FDA for drug approval.

The FDA requires that the drug company provide "proof that a drug has a therapeutic effect in at least some patients," and "no requirements are imposed regarding the 'representativeness'" of a study sample vis-à-vis the population of patients from which it is drawn" (Leber and Davis 1998, p. 179).

Moreover, the FDA does not set any criteria for a *clinically* significant effect, although it generally—as noted above in the "Indications" section—requires demonstration in more than one RCT of a *statistically* significant effect. Thus, drug companies prefer to use a control group in which response is minimized to that associated with unavoidable artifacts of participating in an RCT, because having such a control group maximizes the chance of finding a statistically significant effect. Given that the sample size necessary to demonstrate a statistically significant effect is smallest when the effect size is largest, the easiest way to achieve drug approval is to use very stringent inclusion/exclusion criteria that favor recruitment into the RCT of only those most likely to respond well to the drug (an efficacy trial) and a placebo control group that minimizes the benefit in the control group. Pharmaceutical companies are then doing exactly what they need to do to satisfy FDA requirements to market their drugs.

What the FDA requires or accepts depends on how it interprets the mandate from the U.S. Congress, under which it operates, and what drug companies do is determined by what the FDA requires and accepts. For these reasons, issues related to the use of placebo control groups in RCTs that are performed to establish the efficacy or effectiveness of treatments in clinical populations might well be considered separately from issues related to FDA requirements for drug approval and drug companies' efforts to satisfy those requirements.

However, as described above, the results of studies funded by drug companies to gain FDA approval

of an agent may not generalize to the type of patients clinicians are treating. Even within the limited populations actually studied in some such studies, the clinical benefits of the drug may well be statistically significantly better, but not clinically significantly better, than the effects of withholding treatment (i.e., as in placebo control groups), or the drug's effects may be both statistically and clinically worse than the effects of whatever treatments clinicians are already using for their patients.

Such considerations relate closely to present-day concerns about conflict-of-interest issues when academic researchers are associated with studies funded by drug companies and explain the requirements of many research journals and professional organizations that such conflicts of interests be reported when presenting results of such studies.

In Medical Experiments

Another situation is a medical experiment that is not a clinical trial. Basic researchers in pharmacology, for example, might be interested in the pharmacokinetics of a particular drug in human subjects, not in the efficacy or effectiveness of that drug in any patient population. To test their hypotheses, a control group, randomization, and blinding may also be necessary. However, in many cases, the individuals recruited into such a study are not patients with a disorder but simply volunteers, and the outcomes are focused not on the clinical benefits or harm to patients but rather on aspects of the drug, such as rates of drug absorption and elimination. In many such situations, a placebo control group is the only scientifically valid choice to test hypotheses. Because the focus here is not on establishing the efficacy or effectiveness of a treatment, this is a ***medical experiment*** but is not that specific type of medical experiment called the ***clinical trial.*** Such medical experiments are fundamental to progress in basic science and translational research.

The issues about the use of human subjects in medical experiments, including that of using placebo control subjects, are specific to the particular research question being addressed in a study and are generally different from those in an RCT. These are issues that institutional review boards must assess for each individual research project. Informed consent forms for such studies should not describe the study as an RCT and should spell out clearly that the focus of the study is to further biochemical or pharmacological knowledge about the drug, not (at least not in the near future) to improve treatment for any patients with a disorder.

In Testing a Supplemental Treatment

In many cases, an RCT is performed to test whether a new treatment that is used as a supplement to an established treatment is more effective or efficacious than the standard treatment alone. This is a case in which there are few, if any, reservations to the use of a placebo to control the artifactual effects of offering two treatments rather than one. All patients would receive the standard treatment and then be randomly assigned to supplementation with either the new treatment or a placebo. If researchers find a statistically and clinically significant difference between the two groups, it would represent not an effect of the new treatment but rather an additive or interactive effect of the old and new treatments together. Here few people would have ethical or scientific concerns about the use of a placebo control group.

Placebo Control Groups: Arguments Pro and Con

As we have seen, the arguments against the use of placebo control groups are seldom absolute. Few would argue against using placebo control groups when the usual treatment is no treatment. Few would argue against using placebo control groups when a new treatment is tested as a supplement to an old treatment. The general argument against the use of placebo control groups can be summarized as: There are often better alternatives for a control group than placebo control subjects, alternatives that are better clinically and ethically, and often the scientific quality and clinical impact of RCTs using alternative control groups are preferable.

On the other hand, Leber (2000, p. 699), for example, has argued that "in the evaluation of drugs intended for the management of psychiatric illness, placebo control groups are indispensable, a fact that has been recognized for almost half a century by literally generations of investigators working in the fields of clinical pharmacology and psychopharmacology." Yet A. Bradford Hill (1963), often recognized as the father of RCTs, stated the following: "Is it ethical to use a placebo? The answer to this question will depend, I suggest, upon whether there is already available an orthodox treatment of proved or accepted use." The arguments about placebo control groups among those most knowledgeable about RCTs have been around as long as RCTs have been around (Rothman and Michels 1994).

Arguments for the necessity of placebo control groups are often made on philosophical grounds (Leber 2000) or in terms of convenience to researchers because placebo-controlled RCTs take less time and effort and require less funding (with their smaller sample sizes). However, RCTs are *clinical* trials proposed to address *clinical* issues, not philosophical or logistical ones. To benefit clinical decision making, hence medical consumers and clinicians, the crucial question is this: Is T clinically preferable to C in the population studied? If physicians in the community are using a range of treatments that they believe to be effective, there is little value in demonstrating that a new treatment is better than withholding treatment altogether (as in a placebo control group).

Others argue, not for the necessity of placebo control groups but for their acceptability, that placebos do no *lasting* or *irrevocable* harm. For example, numerous studies have demonstrated that the suicide risk among psychiatric patients receiving a placebo is not such as to preclude the ethical use of placebos in that context (Khan et al. 2000, 2001, 2006; Storosum et al. 2005). However, the Hippocratic oath's requirement to "do no harm" is not restricted to lasting or irrevocable harm. It is not the prerogative of the medical researcher to stipulate how much potential harm to a patient is acceptable. Rather, it is the duty of the medical researcher to assure patients that, to the best of current medical knowledge, the harm that may occur if they participate in the RCT would not be greater than if they chose not to participate in the RCT, and may well be less.

Alternative Control Groups

Treatment-as-Usual Control Groups

For a variety of reasons, from the perspective of a patient or a clinician, the most attractive choice for a comparison group is one that uses what clinicians are currently using: the TAU (treatment-as-usual) control group. Here patients are recruited into the study and randomly assigned either to T, the new treatment under study, or to the treatment they would have received if they had not entered the RCT. The responses in both groups are monitored using the same protocol, with evaluators blinded to group membership. The research question is whether it can be shown, beyond reasonable doubt, that T produces better results than what community clinicians generally achieve.

Because patients who enter such an RCT receive at least the treatment that they would have received had they not entered the RCT (TAU), or perhaps receive a treatment for which there is a rationale and justification for a belief that it might be better (T), such a control group is an inducement to participation. Moreover, since dropping out of the study generally means getting what is now the control treatment, there is little inducement to drop out. Clearly, patients and treatment providers cannot be blinded to the treatment choice, although assessors of treatment response can be.

Objections to this choice of control group generally come from researchers, who correctly point out that community clinicians do not all use the same treatment, and many use treatments that are known to be far from optimal (or use optimal treatment in a less-than-optimal fashion). Far greater variability in response is likely in a TAU control group than there would be if one particular treatment were specified for a control group, or if placebo were used, and greater variability than in the T group.

Consequently, the sample size has to be larger to achieve adequate power than with a specific choice of comparator treatment or with a placebo as the control intervention.

Clearly, with TAU as the control condition, greater detail is needed in reporting results. It is important to report which treatments were being used by community clinicians and to explore whether some of those treatments were likely to be better or worse than T (hypotheses to perhaps be tested in future RCTs). However, all in all, TAU is a viable choice for a control condition in an RCT to document whether T is a better choice in general than what is already available in the community.

Standard-of-Treatment Control Groups

Another viable option is that of selecting and delivering what, on the basis of past, independently replicated RCTs, appears to be the most effective of the treatments in use in the community. This allays many of the problems with TAU control groups, because now the one control treatment can be optimally delivered by research staff, decreasing the heterogeneity within the control group. Also, blinding can now be more complete and effective. Moreover, patients can be assured that current medical knowledge indicates that the treatment in the control group is as good as or better than what they would receive if they were not in the study, which again is an inducement both to participate in the RCT and to not drop out. If there is persuasive evidence that the new treatment T is indeed superior (or at least equivalent) to others currently available, significant findings in such a study might well convince clinicians to use T rather than whatever treatment they had been using.

EQUIVALENCE AND NONINFERIORITY RCTS

The RCT methodology was originally established to establish the efficacy or effectiveness of a treatment, to establish whether T is better than C. In recent years attention has also been paid to issues of clinical significance, as well as to *noninferiority* and *equivalence.* Misconceptions concerning statistical significance, clinical significance, equivalence, and noninferiority have unnecessarily confused the issue of the placebo control.

The basic requirements of an RCT still apply to equivalence and noninferiority trials: the necessity of an appropriate control group, randomization to T versus C groups, blinded assessment of response, and analysis by intention to treat. In the study population, there is an unknown effect size, delta (δ), that is zero when there is absolutely no differential response between T and C, is positive when T tends to be better than C, and is negative when C tends to be better than T. One way of stating the purpose of an RCT is that it is meant to estimate that unknown effect size (Borenstein 1994, 1997, 1998).

The usual two-tailed null hypothesis significance test seeks to prove beyond reasonable doubt that δ is not zero. In designing such a study, a value of δ, the threshold of clinical significance, is designated—say, δ^*. The test is then structured so that when $\delta = 0$, the probability of a significant result is less than, say, 5% (the significance level). When the magnitude of δ is greater than δ^*, the probability of a significant result is greater than, say, 80% (adequate power). Given the fact that when there is sufficient rationale and justification for proposing an RCT there is almost no realistic chance that the effect size is exactly zero, achieving statistical significance in an RCT is generally a matter of having a large enough sample size in a well-designed study with reliable outcome measures. To indicate the possible clinical significance of a statistically significant finding, the effect size and its confidence interval should be reported (as per CONSORT guidelines).

Another way of saying the same thing: with the study design described above, there is a better than 80% probability that a two-tailed 95% confidence interval for the unknown true effect size δ will not include $\delta = 0$, whenever the true effect size is greater than the critical value δ^*.

In contrast, to show that T is clinically superior to C, one needs to show that the entire confidence interval for that effect size is greater than δ^*. To show that T and C are clinically equivalent, one

needs to show that the confidence interval lies completely between $-\delta^*$ and δ^*. To show the noninferiority of T to C, one needs to show that the entire confidence interval is less than $-\delta^*$.

One can always demonstrate either noninferiority or equivalence, simply by using unreliable outcome measures, allowing deviations from treatment and measurement protocols, etc. That is, a badly conducted trial will result in an attenuated effect size between any two drugs, an effect size closer to zero, that can almost always be labeled as a noninferior or equivalent result.

This issue is highly relevant to the valid interpretation of study results because of a common confusion between a result being *non–statistically significant* and two drugs showing *equivalence.* To report a non–statistically significant result is only to admit that the sample size was not large enough, the design not powerful enough, or the measures not reliable enough to demonstrate beyond reasonable doubt that $\delta \neq 0$. That is nowhere near the same thing as reporting a demonstration beyond reasonable doubt that $-\delta^* < \delta < \delta^*$ (i.e., equivalence). As the old saying goes: "Absence of proof is not proof of absence."

In particular, if one randomly assigned subjects in an RCT to one of two treatment groups (T1 or T2) or to a placebo control group (C) and found no statistically significant difference between T1 and T2 but found statistically significant differences both between T1 and C and between T2 and C, that tells nothing about the possible clinical equivalence of T1 and T2. All one would know is that both T1 and T2 were shown to be better than (not necessarily even clinically superior to) placebo; the sample was not large enough to detect whatever difference there might be between T1 and T2. Any conclusion comparing T1 and T2 would be exactly the same whether or not the placebo control group were included in the design. Yet many arguments for the use of a placebo control group inappropriately reflect an effort to use the placebo control as a decoy to interpret results comparing T1 and T2.

But finally, why would it be important to establish beyond reasonable doubt the clinical equivalence of two treatments, particularly when such a result can be obtained through poor study design (e.g., choice of measurement) and execution of the RCT? Often when this question is asked, whether of a drug company representative or of an academic researcher, a complete answer often contains an implicit reinterpretation of equivalence as superiority. For example: Two treatments might have equivalent effects in reducing symptoms, but one might have a better side-effect profile. Or the two treatments might have equivalent effects in terms of both symptom reduction and side effects, but one may be far less costly or have greater ease of use than the other. In all such cases, the goal of the RCT should be to establish the clinical preference for one treatment or the other over the control condition by using an outcome measure sensitive to the specific ways one drug might be clinically preferable to another. But that would then be not an equivalence study but rather the usual type of RCT, with a primary outcome reflecting the particular way in which T is hypothesized to be superior to C.

STATISTICAL ANALYSIS AND POWER

Threaded through all the above issues are implicit considerations of statistical analysis and power. Every single decision about research design has some impact on the appropriate choice of analysis and on the power to detect clinically significant effects. In fact, the major difference between well-designed and well-executed present-day RCTs and those done 50 years ago stems from advances in methods of statistical analysis of results and better understanding of the concept and application of power in designing RCTs.

With the simplest possible design, randomly assigning a representative sample of patients to a treatment (T) or control (C) condition, with a binary primary outcome—"success" versus "failure"—the analytic method would be a 2 x 2 (treatment x outcome) χ^2 test. This is the least powerful design (Cohen 1983; Kraemer 1991; Kraemer and Thiemann 1987, 1989; MacCallum et al. 2002), and the study thus requires perhaps twice, perhaps 10 times, as many patients for adequate power compared

with studies with other designs. A valid choice? Yes. A wise choice? No.

Suppose we merely substituted that binary primary outcome with a dimensional one—for example, symptom level at the end of treatment—and proposed to use the most common RCT analysis method: the two-sample *t* test. Immediately, there would be an increase of power (thus requiring a smaller sample size for adequate power). If the goal is to detect a moderate effect (number needed to treat [NNT] ≅4), for a 5% two-tailed test one would require 63 patients per group or a total of 126 patients. Detecting a small effect (NNT ≅9) would require 389 patients per group, and detecting a large effect (NNT ≅2) would require only 26 patients per group.

The two-sample *t* test is valid when the outcomes being measured are approximately normally distributed with equal variances in the two groups, but many clinically meaningful outcomes have asymmetrical distributions, have long tails, or occur with unequal variances in the two groups. Then one might use instead the nonparametric Wilcoxon rank sum test (Mann-Whitney test). When the *t* test gives valid results, the Mann-Whitney test is also valid and has quite similar power. However, the nonparametric test is valid in many circumstances when the *t* test is not. This illustrates two general principles: the choice of the outcome measure must be in accordance with the choice of the analytic procedure, and better selection of the outcome measure has a major impact on the study's power and thus the necessary sample size.

If one uses any of the above for an RCT of depressed patients, most of the sample would be female; for an RCT of schizophrenic patients, most of the sample would be male. In many cases, it is proposed to stratify such sample populations in order to equalize the representation of males and females. Is this wise?

If it is decided that stratification is warranted, to be valid the analytic procedure must acknowledge that stratification. For a binary outcome, one might use a logistic regression analysis and for a dimensional outcome, a linear regression analysis, with treatment group, stratum (here, gender), and their interaction as independent variables in each case.

One common analytic error is to assume that the interaction does not exist and to use analysis of covariance with gender as the covariate. If that interaction does exist in the study population and is ignored in the analysis, it often compromises the significance level, and thus the validity of the test, and almost inevitably reduces the power. But if the interaction is included in the analysis, care must be taken to properly center all the independent variables to produce clinically interpretable results (Kraemer and Blasey 2004).

If this is done correctly, the interaction test assesses whether the treatment effect in women is different from the effect in men, and the main effect of treatment assesses whether the average treatment effect across men and women is nonrandom. When there is an interaction effect in the study population, the main effect of treatment in this analysis is not the same as the effect of treatment assessed in an unstratified sample. The crucial issue then is which treatment effect is of interest—the effect in the total population or the average effect across the subpopulations defined by the strata.

If the decision is that the sample should be stratified, the sample size needed for adequate power is likely to increase, and the logistical difficulty of accumulating a stratified sample is likely to be much greater. If, for example, 80% of those with the disorder of interest are women, but it is decided that 50% of the sample in the RCT should be women, one will have to work much harder to recruit that oversampling of men into the study. Thus, careful thought should be given to whether the rationale and justification for stratification are strong enough to necessitate larger samples, more complex analyses, and a shift in the hypothesis being tested.

The difficulty of such decisions is exacerbated when researchers (or reviewers) seek to control for

multiple covariates (e.g., gender, age, ethnicity, initial severity of the disorder). To truly control the study for the effects of such variables, one stratifies the sample. However, with gender (two possibilities), age (say, five age groups), ethnicity (say, five ethnic groups), and initial severity (say, three levels), one has 2 x 5 x 5 x 3 = 150 strata, and one would have to recruit adequate numbers into each stratum (for optimal power, an equal number into each stratum). If even a minimal number of patients per stratum were specified, say, 10 per stratum (5 randomized to T and 5 to C), the minimal sample size would be 1,500!

If these stratification variables are not very strongly associated with treatment effect, the result is a study with less power than would be achieved with a simple design. If there are collinearities among these variables (say, women and older patients tend to have high higher initial disease severity), the power to detect treatment effects might also be reduced. One of the least wise decisions in RCT design is to try to control for the effects of too many variables, and many experienced biostatisticians argue against any stratification of the sample unless the primary hypotheses concern moderators of treatment outcome.

Researchers and review committees, however, often propose another tactic: Instead of controlling for the effects of these baseline variables through stratification, adjust for them in a mathematical model. Now the sample would continue to be 80% women, but the analysis would include consideration of both treatment and gender. What then often happens in analysis is exclusion of all interactions. Without adjustment, the two-sample *t* test has $N - 2$ degrees of freedom (the larger the number of degrees of freedom, other things being equal, the greater the power), but with a single covariate, that becomes $N - 4$ ($N - 2^2$), and with four covariates, it becomes $N - 32$ ($N - 2^5$). As noted above, if such interactions exist in the study population and are excluded in the model, the significance level may be compromised and power is almost inevitably lost. Thus, if covariates are to be included, their interactions must be as well. Unless inclusion of those variables has a major strengthening effect on effect size, this inevitably means a loss of power. Finally and perhaps most important, collinearity effects resulting from associations between the variables included cost even more power. Again, most experienced biostatisticians argue against adjusting for the effects of baseline variables in the absence of a strong rationale and empirical justification for doing so.

On the other hand, in a multisite RCT, stratification by site is built into the design and must be included in the analysis, and even then, many researchers and reviewers choose to ignore it. Multisite RCTs often show that site differences are a major source of variance in the outcome measurements (MTA Cooperative Group 1999). The most convincing demonstration of the almost-ubiquitous nature of site differences is not from an RCT but from a study of inbred strains of mice in a genetics study (Crabbe et al. 1999) under controlled laboratory conditions. Even then, site differences occurred. In an RCT, if samples are drawn from different sites, or in different time spans, or at the same site at the same time but using different recruitment strategies (e.g., referrals from doctors versus responses to advertisement), one should always expect that these differences will affect the primary outcome. Thus, randomization must be done within each such stratum, and comparison of T versus C must be a pooled comparison of the within-stratum comparisons of T versus C (Kraemer and Robinson 2005).

Thus far we have focused on assessing a single primary outcome at the end of treatment, whether a binary success/failure or a dimensional outcome, and have recommended against using a binary outcome. But, some would argue, some outcomes are by their nature binary: either the patient dies or not, the patient recovers or not, the disease remits or not. Are we not then obliged to use a binary outcome, and "take the hit" by increasing the sample size manyfold?

Outcomes such as these occur over the course of time, and at different times for different patients. By simply reorienting the analysis to examination of the time to the event, one moves from a binary outcome to a dimensional one. This is the situation in which survival analyses become the analytic procedure of choice: Kaplan-Meier estimation-of-survival curves within each group (Kaplan and Meier

1958), comparison of these survival curves in the T versus C groups, and use of the Cox proportional model (Andersen et al. 1985), for example, when there are strata or covariates to be considered. Although the sample sizes for adequate power will be somewhat greater than with other dimensional outcomes (because some patients will be censored, i.e., they will not have had the outcome occur before the end of study), the sample size here will be much smaller than when using a binary outcome, and more useful clinical information will be obtained.

Also, with dimensional outcome measurement, modern analytic tools can lead to increased power without increasing sample size. For example, instead of assessing the outcome using only the endpoint of treatment, one could assess that outcome measure at baseline and at fixed times during the treatment period. Random regression models (also known as hierarchical models, or growth curves; Berger 1986; deLeeuw and Kreft 1986; Ware 1985) basically model the trajectory of response within each patient and then test whether the trajectories of response in the T group are clinically preferable to those in the C group. Because multiple measures per patient are used to characterize each patient's response, reliability is increased, and thus power is increased. Moreover, in the case of missing data or dropouts, partial data on the trajectory per patient enable stronger imputation methods to facilitate intention-to-treat analyses. Quite aside from the multiple statistical advantages of designing studies with repeated measures of outcomes over time, such information is often clinically informative in guiding clinicians to recognize early those patients who are unlikely to ever respond to a given treatment.

This discussion barely scratches the surface of analytic methods available, but illustrates two general principles:

1. For adequate power and to best inform clinical decision making, characterize the response of each individual patient as precisely and concisely as possible (using reliable measures, preferably dimensional, with repeated measures over time). That might sometimes complicate the analysis, but analytic methods are generally available to take advantage of such precision.
2. Design the study to answer the primary research question, not to answer all possible questions that might arise. Leave those to secondary or exploratory post hoc analyses. Do not stratify the study population unless the design requires multiple sites or recruitment sources or the primary research question is about the strata. Do not try to control or adjust for all possible influences on treatment effect; instead, focus on controlling those factors empirically shown to strongly influence treatment effect.

SUMMARY

The sine qua non of an RCT is that there be a control or comparison group, with an appropriate sample of patients randomly assigned to the treatment and control groups, with blinded assessment of outcome, and with analysis by intention to treat. A reasonable analogy of conducting an RCT is that it is like juggling many balls, trying to keep them all in the air at the same time: choice of control group, randomization, blinding, sampling, treatment protocol, measurement protocol, and fidelity to the protocols during the study, analysis, and interpretation of results, etc. The more research questions that are to be addressed in a particular RCT, and the more complex each research question is, the more balls are being juggled and the more slippery they are. Moreover, as soon as one ball drops, the others are likely also to follow. Any mistake in sampling, for example, is likely to have repercussions in analysis and interpretation of results. Poor measurement (e.g., use of a binary primary outcome) will have an effect on design (sample size). Improved design (e.g., repeated measures of the primary outcome) will have an effect on analysis and interpretation of results. For this reason, the best studies result when there is a focus on the primary research question, when all research decisions are made to protect the integrity of and amplify the answers to that primary research question. When the effort is made to answer as many questions as possible in one study, e.g., addressing multiple outcomes, or controlling or adjusting for multiple variables, RCTs tend not to answer any research questions well at all.

The choice of an appropriate control group is context specific but should take into consideration ethical and clinical as well as scientific issues. On the issue of using placebo control groups, we distinguished RCTs to establish the efficacy or effectiveness of a drug from studies done for the purpose of gaining FDA approval of a drug versus randomized medical experiments to explicate basic science questions, which are often performed with subjects who are not patients and for purposes that have little or nothing to do with efficacy or effectiveness of treatments.

We have discussed in detail when it is best and least controversial to use a placebo control group (i.e., when there is no better alternative to placebo) and when it may be more appropriate to use a TAU control group or a standard-of-care control group, particularly in cases where withholding treatment, as would be done with placebo control subjects, raises ethical questions as well as logistical questions.

Using placebo control groups as a foil to understand differences not seen between two active treatments is often based on a misinterpretation of statistical significance. Moreover, use of placebo control groups as an aid in establishing equivalence or noninferiority is questionable, because what may appear to be equivalence is often related to poor study execution rather than to actual equivalence between treatments. Also, it is not clear why equivalence is important to clinical decision making.

In short, in some circumstances using a placebo control group is the only choice, and in others using a placebo control group is the best choice. There are also circumstances in which ethical, clinical, and scientific interests are best served by using other types of control groups. Finally, there have been circumstances in which inclusion of placebo control groups has misled thinking about the effects of other drugs.

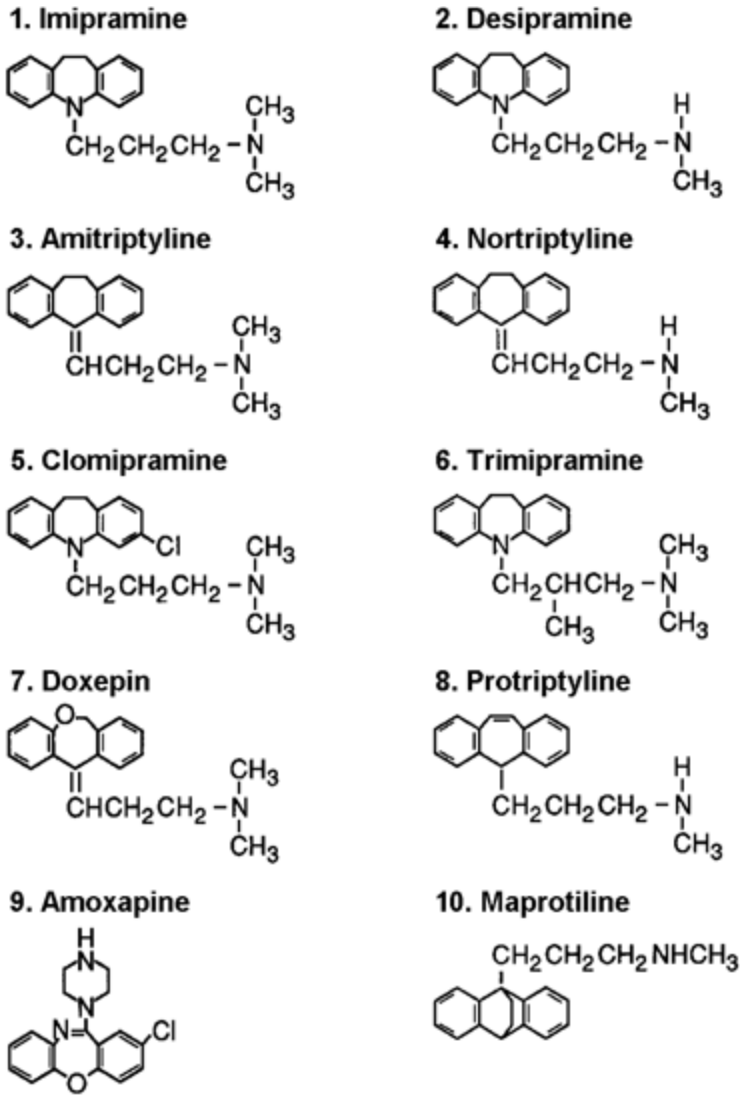
Chapter 12. Tricyclic and Tetracyclic Drugs

TRICYCLIC AND TETRACYCLIC DRUGS: INTRODUCTION

The tricyclic antidepressant agents hold an important place in the history of treatments for depression. They were the first class of antidepressant compounds to be widely used in depression and remained the first-line treatment for more than 30 years. The observation of their activity led to theories of drug action involving norepinephrine and serotonin. Indeed, this "psychopharmacological bridge" suggested that alterations of these neurotransmitters might cause depression (Bunney and Davis 1965; Prange 1965; Schildkraut 1965). The tricyclics were extensively studied, and through this study the field developed several principles for the management of depressive illness. For example, in addition to understanding the need for adequate dose and duration during acute treatment, the importance of continuation treatment was described. The adverse events associated with these agents required that psychiatrists become familiar with a variety of syndromes, such as anticholinergic delirium, delayed cardiac conduction, precipitation of acute glaucoma, and orthostatic hypotension. The observation that tricyclic plasma concentrations varied widely stimulated interest in understanding the metabolism of tricyclics. The field was introduced to the concepts of polymorphisms in the mephenytoin and debrisoquine pathways (later relabeled the cytochrome P450 [CYP] 2C19 and 2D6 pathways), which in part explained the widely varying blood levels. Knowledge of the widely varying drug concentrations raised questions about the relationships of clinical activity and drug concentrations. Although effects of antipsychotics and a few other drugs on tricyclic plasma levels had been described in the 1970s, it was the observation of the effect of fluoxetine on desipramine coupled with the aggressive marketing of the selective serotonin reuptake inhibitors (SSRIs) that greatly expanded our awareness of and knowledge about drug interactions. Finally, our knowledge of how these drugs worked became the basis for the discovery of new drugs such as the SSRIs.

HISTORY AND DISCOVERY

Although iminodibenzyl had been synthesized in 1889 (Byck 1975), it was not until after 1948 that derivatives of this compound were investigated for their potential usefulness in human subjects. Ironically, the properties that were of interest—the antihistaminic and sedative actions—would later be viewed as the "side effects" of these compounds. In the 1950s, investigation of one of these compounds led to the serendipitous observation that chlorpromazine had "antipsychotic" effects (Delay and Deniker 1952). The tricyclic compound imipramine was closely related to chlorpromazine, differing only in the substitution of an ethylene linkage for sulfur. In 1957, Roland Kuhn, a Swiss psychiatrist, investigated the clinical effects of imipramine in human subjects in part to determine if its sedative properties would be useful (Kuhn 1958, 1970). He found that imipramine was not useful for calming agitated patients; however, he observed that it did appear to ameliorate symptoms in depressed patients. As with lithium and chlorpromazine earlier, the discovery of the psychotropic effects of the tricyclics was a chance observation.



After imipramine was introduced, several other antidepressant compounds were developed and marketed. These compounds had a basic tricyclic structure and also shared many of the secondary effects for which the tricyclics came to be known. Later, other heterocyclic compounds, such as

maprotiline, were also marketed. These agents had somewhat similar structures and secondary effects.

STRUCTURE–ACTIVITY RELATIONS

Tricyclic and tetracyclic compounds are categorized on the basis of their chemical structure (Figure 12–1). The tricyclics have a central three-ring structure, hence the name. The tertiary-amine tricyclics, such as amitriptyline and imipramine, have two methyl groups at the end of the side chain. These compounds can be demethylated to secondary amines, such as desipramine and nortriptyline. The tetracyclic compound maprotiline (Ludiomil) has a four-ring central structure. Five tertiary amines have been marketed in the United States—amitriptyline (Elavil), clomipramine (Anafranil), doxepin (Sinequan), imipramine (Tofranil), and trimipramine (Surmontil). The three secondary-amine compounds are desipramine (Norpramin, Pertofrane), nortriptyline (Aventyl, Pamelor), and protriptyline (Vivactil). All of these compounds, in addition to amoxapine (Asendin) and maprotiline (Ludiomil), have been approved for use in major depression with the exception of clomipramine (Anafranil), which in the United States is approved for use only in obsessive-compulsive disorder (OCD).

Although the tricyclics are named for their central three-ring structure, the nature of the side chain appears more important for their function. The tertiary tricyclics—amitriptyline, imipramine, and clomipramine—are more potent in blocking the serotonin transporter. The secondary tricyclics are much more potent in blocking the norepinephrine transporter (Table 12–1) (Bolden-Watson and Richelson 1993; Tatsumi et al. 1997).

Source. Uptake potency data adapted from Tatsumi et al. 1997. Receptor affinity data adapted from Richelson and Nelson 1984.

The nature of the central three-ring structure produces other differences. For example, amitriptyline and nortriptyline share a similar dibenzocycloheptadiene structure, although their side chains are identical to those of imipramine and desipramine, respectively. Similar to the imipramine–desipramine pair, amitriptyline and nortriptyline have similar differences in potency in blocking the serotonin and norepinephrine transporters; however, compared with imipramine, amitriptyline is more

anticholinergic and antihistaminic, has greater α_1-adrenergic receptor blockade, and is somewhat more potent in blocking the serotonin transporter (see Table 12–1) (Cusack et al. 1994; Richelson and Nelson 1984; Tatsumi et al. 1997).

Of the tricyclics, clomipramine is the most potent in blocking the serotonin transporter, although its metabolite desmethylclomipramine is a potent norepinephrine reuptake inhibitor (Hall and Ogren 1981). Doxepin is structurally most similar to amitriptyline but is more similar in functional potency to imipramine (Pinder et al. 1977). Doxepin is the most antihistaminic of these compounds. Protriptyline is structurally most similar to nortriptyline but is more slowly cleared (has a longer elimination half-life) and is given in doses about one-third those of nortriptyline (Moody et al. 1977).

The structure of amoxapine differs from the structures of the other tricyclics. With a central three-ring structure and a side chain that differ from those of the tricyclics, amoxapine is structurally more similar to the neuroleptic loxapine, from which it is derived. Similar to the secondary tricyclics, it is a potent norepinephrine reuptake inhibitor. Unlike all of the other compounds in this group, amoxapine, and particularly its metabolite 7-hydroxyamoxapine, blocks postsynaptic dopamine receptors (Coupet et al. 1979). As a result, it is the only compound in the group that has antipsychotic activity in addition to antidepressant effects.

Maprotiline also differs from the others in this group. Although maprotiline is referred to as a heterocyclic or tetracyclic, these terms do not explain its inclusion in the group. The side chain, however, is identical to that in desipramine, nortriptyline, and protriptyline. As would be predicted from this similarity, maprotiline is most potent in blocking the norepinephrine transporter (Randrup and Braestrup 1977).

As discussed below, it is important to remember that in humans, the tertiary tricyclic compounds are demethylated to secondary tricyclic compounds, all of which are potent norepinephrine reuptake inhibitors. As a result, when these tertiary compounds are administered to human subjects, the effects of both the metabolite and the parent have to be taken into account.

PHARMACOLOGICAL PROFILE

Reuptake Blockade

Early in the history of the tricyclic and tetracyclic antidepressants, the ability of these compounds to block the transporter site for norepinephrine was described (Axelrod et al. 1961) (see Table 12–1). The tertiary amines have greater affinity for the serotonin transporter, whereas the secondary amines are relatively more potent at the norepinephrine transporter. During the administration of amitriptyline, imipramine, or clomipramine, these tertiary amines are demethylated to secondary amines; thus, both serotonergic and noradrenergic effects occur. In addition, because dopamine is inactivated by norepinephrine transporters in the frontal cortex (Bymaster et al. 2002), norepinephrine reuptake inhibitors would be expected to increase dopamine concentrations in that region.

Receptor Sensitivity Changes

The initial reuptake blockade described above is followed by a sequence of events (Blier et al. 1987; Charney et al. 1991; Tremblay and Blier 2006). The tertiary tricyclic compounds inhibit the uptake of serotonin, and serotonin levels rise. As the result of inhibitory feedback from the presynaptic somatodendritic serotonin$_{1A}$ (5-HT$_{1A}$) autoreceptor, the firing rate of the presynaptic serotonin neuron falls, and concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin, decline rapidly. During a 10- to 14-day period, the presynaptic autoreceptor is desensitized, and at this point, the tonic firing rate returns to its pretreatment rate. With both a normal firing rate and reuptake blockade, serotonin transmission is enhanced.

The tricyclic agents also sensitize or upregulate postsynaptic 5-HT_{1A} receptors (de Montigny and Aghajanian 1978). These changes further enhance the effects of serotonin. The changes in pre- and postsynaptic receptor sensitivity occur over a 2-week period. Consequently, the timing of these changes is more consistent with the onset of early antidepressant response than with the initial uptake blockade (Charney et al. 1991).

The tricyclics also have actions at the 5-HT_2 receptor. Depression is associated with an increase in postsynaptic 5-HT_2 receptor density (Arora and Meltzer 1989; Cheetham et al. 1988; Stanley and Mann 1983; Yates et al. 1990). A variety of antidepressants, including the tricyclics, downregulate the 5-HT_2 receptors (Goodwin et al. 1984; Peroutka and Snyder 1980). The 5-HT_2 receptors mediate excitatory effects, whereas the $5HT_{1A}$ receptors generally have inhibitory effects; thus, these two systems act in opposition. In preclinical experiments, when the 5-HT_2 receptor was blocked by an antagonist, the effects of serotonin were enhanced (Lakoski and Aghajanian 1985; Marek et al. 2003). Some of the tricyclics—particularly doxepin, amitriptyline, and amoxapine—have 5-HT_2 antagonist properties relatively comparable to their reuptake potency (see Table 12–1) (Tatsumi et al. 1997). These properties should enhance their serotonergic effects.

The sequence of events with chronic dosing in the noradrenergic system is more complicated (Tremblay and Blier 2006). As in the serotonergic system, reuptake inhibition results in a rapid decline in norepinephrine turnover, as reflected by a fall in concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, and attenuation of the firing rate of the noradrenergic neuron. This effect appears to be mediated by the presynaptic somatodendritic α_2-adrenergic autoreceptor, which provides inhibitory feedback to the presynaptic neuron. In contrast to the serotonergic system, the firing rate of noradrenergic neurons remains inhibited with chronic treatment (Szabo and Blier 2001), suggesting that somatodendritic α_2 receptors do not desensitize. Norepinephrine concentrations do increase at postsynaptic sites such as the hippocampus and frontal cortex. This may indicate desensitization of terminal α_2 autoreceptors.

With chronic treatment, the postsynaptic β-adrenergic receptor is downregulated or decreased in density. In fact, downregulation of the β-adrenergic receptor was once proposed as a mechanism of tricyclic action (Sulser et al. 1978; Vetulani and Sulser 1975). Current evidence suggests that β-adrenergic receptor downregulation is more likely a compensatory change. Overall, chronic administration of a noradrenergic reuptake inhibitor appears to override the downregulation of the postsynaptic β-receptor, resulting in enhanced noradrenergic transmission. This effect is manifested as enhanced formation of the second messenger cyclic adenosine monophosphate (cAMP) (Duman et al. 1997) and is reflected clinically by a persistent increase in heart rate (Roose et al. 1998; Rosenstein and Nelson 1991).

Alternatively, some of the actions of noradrenergic reuptake inhibitors may be mediated by postsynaptic α_1 and α_2 receptors, which do not appear to be downregulated during chronic treatment. The net effect of norepinephrine reuptake inhibitors on noradrenergic transmission during chronic treatment is further complicated by regional differences in the adrenergic receptors. Nevertheless, the antidepressant effects of norepinephrine reuptake inhibitors do appear to be mediated by norepinephrine, because inhibition of catecholamine synthesis with α-methyl-*p*-tyrosine (AMPT) results in relapse of depressive symptoms (H. L. Miller et al. 1996).

Secondary Effects

The tricyclic and tetracyclic compounds also have a variety of other actions mediated by other receptors (Cusack et al. 1994; Richelson and Nelson 1984) (see Table 12–1). For example, these compounds block muscarinic receptors, producing anticholinergic effects. Although these anticholinergic effects have generally been thought to mediate adverse effects, a recent double-blind, randomized crossover study in 19 subjects with major depression found that the anticholinergic drug

scopolamine had a beneficial effect on depressive and anxious symptoms (Furey and Drevets 2006). The tricyclics also block histamine$_1$ (H_1) receptors and α_1- and α_2-adrenergic receptors, resulting in a variety of other effects (as discussed in the next section). Tricyclics act on fast sodium channels, which explains their adverse cardiac effects. Although the actions of tricyclics on sodium channels have traditionally been considered problematic for patients with depression, these same actions may contribute to the beneficial effects of tricyclics on pain (Priest and Kaczorowski 2007). The potency of secondary effects of the tricyclics and tetracyclics varies considerably. Amitriptyline is the most anticholinergic not only of the agents in this group but also of all antidepressants. Desipramine is the least anticholinergic among the tricyclics. Doxepin is the most potent H_1 antagonist in this group, although another antidepressant, mirtazapine, is even more potent. The consequences of these secondary effects are discussed below.

PHARMACOKINETICS AND DISPOSITION

Absorption

Absorption of the tricyclic and tetracyclic drugs occurs in the small intestine and is rapid and reasonably complete. Peak levels are reached within 2–8 hours following ingestion. Exceptions include protriptyline (peak levels reached between 6 and 12 hours after ingestion) and maprotiline (peak levels not reached until 8 hours or longer). Although peak levels may have implications for side effects, which can occur quickly, the timing of peak levels is relatively unimportant with respect to efficacy because the antidepressant action of these drugs occurs over several weeks.

Volume of Distribution

The tricyclic and tetracyclic compounds are basic lipophilic amines and are concentrated in a variety of tissues throughout the body. As a result, they have a high volume of distribution. For example, concentrations of these drugs in cardiac tissue exceed concentrations in plasma.

Plasma Protein Binding

The tricyclic and tetracyclic compounds are extensively bound to plasma proteins (e.g., 90% or greater) because of their lipid solubility. Exceptions are the hydroxy metabolites, which have lower plasma protein binding than the parent compounds.

First-Pass Metabolism

Following absorption, the tricyclics are taken up in the circulation but pass first through the liver, and metabolism of the drug begins—the so-called first-pass effect. As a result, the amount of the compound that enters the systemic circulation is reduced.

Hepatic Metabolism

Hepatic metabolism is the principal method of clearance for the tricyclic and tetracyclic compounds. Only a small portion of drug is eliminated by the kidney. Rates of hepatic metabolism vary widely from person to person, resulting in dramatic differences in steady-state plasma concentrations. Elimination half-lives for most of the tricyclic and tetracyclic compounds average about 24 hours or longer; thus, the drugs can be given once a day (Table 12–2). Amoxapine has a shorter half-life than the other tricyclics and is an exception.

Hepatic metabolism of the tricyclics and tetracyclics occurs along two principal metabolic pathways. *Demethylation of the side chain* converts the tertiary amines to secondary amines—for example, amitriptyline is converted to nortriptyline—and the characteristics of the compound are altered. The tertiary amines are relatively more serotonergic, whereas the demethylated amines are relatively more noradrenergic. The other pathway in hepatic metabolism is *hydroxylation of the ring structure.* Hydroxylation results in the formation of hydroxy metabolites. In some cases, the levels of the metabolite are substantial. The concentration of 10-hydroxynortriptyline usually exceeds that of the parent compound (Bertilsson et al. 1979). Usually 2-hydroxydesipramine is present at levels approximately 40%–50% of those present in the parent compound, but these ratios are quite variable, depending on the rate of hydroxylation (Bock et al. 1983; Potter et al. 1979). Thus, in extensive metabolizers, the ratio of hydroxy metabolite to parent compound can be quite high, but total drug levels are low. Hydroxyimipramine and hydroxyamitriptyline are present at very low concentrations and are clinically unimportant. The hydroxy metabolites are then conjugated and excreted. The conjugated metabolites are not active.

Hydroxynortriptyline and hydroxydesipramine both block the norepinephrine transporter (Bertilsson et al. 1979; Potter et al. 1979). Both have been shown to have antidepressant activity (Nelson et al. 1988b; Nordin et al. 1987). The potency of hydroxydesipramine is comparable to that of the parent compound in terms of norepinephrine reuptake blockade. There are two isomers of hydroxynortriptyline, *E*- and *Z*-10-hydroxynortriptyline. *E*-10-hydroxynortriptyline is present at levels four times higher than those of the *Z* isomer and is about 50% as potent as nortriptyline in blocking norepinephrine uptake. The clinical significance of high levels of less potent hydroxynortriptyline is not entirely clear. In particular, it is not clear whether high levels of less potent hydroxynortriptyline

might interfere with the action of nortriptyline—a question of interest because such an effect might explain the therapeutic window described for this drug. Both hydroxynortriptyline and hydroxydesipramine are less anticholinergic than their parent compounds. The hydroxy metabolites may have other effects. Early studies suggested that hydroxynortriptyline concentrations were disproportionately associated with cardiac conduction abnormalities (Schneider et al. 1988; Young et al. 1985), but later studies indicated that the E enantiomer of 10-hydroxynortriptyline was less cardiotoxic (Pollock et al. 1992).

The principal metabolic pathway for amoxapine is hydroxylation, during which 7-hydroxyamoxapine and 8-hydroxyamoxapine are produced (Coupet et al. 1979). These compounds differ: 7-hydroxyamoxapine has high-potency neuroleptic properties but a short half-life; 8-hydroxyamoxapine is metabolized more slowly and appears to contribute to the drug's antidepressant action.

In recent years, identification of the specific isoenzyme pathways involved in the metabolism of a variety of drugs, including the tricyclics, has been the focus of intensive study. The CYP2D6 pathway appears responsible for hydroxylation of desipramine and nortriptyline (Brosen et al. 1991). In fact, desipramine has been considered the prototypic substrate for CYP2D6 because it has no other major metabolic pathways. Demethylation of the tertiary-amine compounds appears to involve a number of CYP isoenzymes, including 1A2, 3A4, and 2C19. These hepatic isoenzymes are under the control of specific genes, and the gene loci have been identified for several of these isoenzymes, including CYP2D6. Approximately 5%–10% of Caucasians are homozygous for the recessive autosomal 2D6 trait, resulting in deficient hydroxylation of desipramine and nortriptyline (Brosen et al. 1985; Evans et al. 1980). These individuals are termed *poor metabolizers,* while those with adequate 2D6 enzyme are referred to as *extensive metabolizers.* Approximately 20% of individuals of Asian descent have a genetic polymorphism resulting in deficient CYP2C19 metabolism. This pathway is involved in the metabolism of the tertiary tricyclic compounds.

The variability in plasma concentrations that results from these metabolic differences is substantial. For example, in a sample of 83 inpatients who were given a fixed dose of 2.5 mg/kg of desipramine, we observed steady-state plasma concentrations ranging from 20 ng/mL to 934 ng/mL (Nelson 1984). Even among extensive metabolizers, there can be variability in the rates of metabolism, resulting in the term *ultrarapid metabolizers.* Various methods have been used to phenotype the individuals who are slow or fast metabolizers. For example, formation of the debrisoquine metabolite in the urine has been used to characterize the metabolic rate of CYP2D6 (Brosen et al. 1991; Evans et al. 1980). Recent work in this area has shifted to genotyping the involved isoenzymes. In clinical practice, blood levels of the compounds themselves are more often used as a crude index of the rate of metabolism.

As noted above, desipramine has often been used as a substrate for 2D6 because 2D6 is the only major metabolic pathway for this compound. While desipramine may be useful for examination of 2D6 inhibition, it may overestimate the magnitude of drug interactive effects for those agents that have multiple pathways.

Steady-State Concentrations

Steady state is an important pharmacological concept for clinicians to understand if drug monitoring is employed. Steady state is that point, on a fixed dose, at which plasma concentrations of the drug reach a plateau. Steady state is achieved after five half-lives. At this point, the concentration of the drug should be 97% of the maximal concentration achieved for that dose. In fact, after three half-lives, the drug will have achieved about 87% of the steady-state concentration. If blood level monitoring is employed, a sample is drawn before the next dose is given, usually in the morning after the patient's level has reached a steady state. Steady-state drug concentrations should remain

relatively stable as long as the dose is constant, the patient is compliant, and no interactive drugs are added.

The day-to-day biological variability of drug concentrations at steady state is not frequently described. In inpatients at steady state, the coefficient of variation (SD/mean) of desipramine is approximately 10%–15% (J. C. Nelson, unpublished data, 1985). In outpatients, this variability may increase. This means that if the average plasma concentration is 150 ng/mL, two-thirds of samples obtained will be ±10%, or between 135 ng/mL and 165 ng/mL. Research studies of drug concentrations usually employ an average of two or three plasma samples to reduce the effect of this variability. If only one sample is drawn, the clinician needs to remember that even if the laboratory error is low, there will be moderate biological variability. Single blood levels are better viewed as estimates than as precise measures.

When the drug concentration is measured, the total of both the free and bound drug is reported. Few laboratories are prepared to measure free levels, yet drug concentrations in the cerebrospinal fluid are proportional to the free levels. The *free concentration* is dependent on dose and hepatic clearance but is not affected by plasma protein binding (Greenblatt et al. 1998). The latter is often misunderstood. Factors that affect plasma proteins—malnutrition, inflammation—may lead to changes in the bound fraction, but the absolute free concentration is unaffected. If another drug affects binding, the absolute free concentration remains unaffected. In these instances, the *free fraction* may change because the bound portion declines, not because there is a change in the free concentration.

Linear Kinetics

Most of the tricyclics have linear kinetics; that is, concentration increases in proportion to dose within the therapeutic range. There are exceptions. Desipramine, for example, appears to have nonlinear kinetics in the usual dose range (Nelson and Jatlow 1987). Rapid metabolizers of desipramine are most likely to display nonlinear changes during the time when the dose is increasing. In these patients, a disproportionate rise in the drug concentration occurs when the dose is increased. In cases of overdose, nonlinear changes are more likely to occur, and the clinician cannot assume that usual rates of drug elimination will be maintained.

Effects of Aging

Many changes in the pharmacodynamics and pharmacokinetics of drug treatment occur with aging, yet some may be relatively unimportant (Greenblatt et al. 1998). The ratio of fat to lean body mass increases, and cardiac output and hepatic blood flow decrease. There may be further changes associated with medical illness. But the clinical importance of these changes is usually relatively minor because of the dramatic variability of hepatic metabolism. Age-related changes in metabolism vary with the isoenzymes involved. The activity of the CYP3A4 pathway does slow with age (von Moltke et al. 1995). Most studies of the tertiary amines, such as imipramine, suggest that concentrations of these drugs are increased somewhat in older individuals (Abernathy et al. 1985; Benetello et al. 1990; Furlanut and Benetello 1990). Alternatively, most studies of nortriptyline (Bertilsson 1979; Katz et al. 1989; Smith et al. 1980; Young et al. 1984; Ziegler and Biggs 1977) and desipramine (Abernathy et al. 1985; Nelson et al. 1985, 1995) indicate that ratios of blood level to dosage of these drugs are relatively unaffected by aging, suggesting that the 2D6 isoenzyme is not similarly affected. In addition, the relationship of nortriptyline and desipramine plasma concentrations to therapeutic effects appears to be relatively similar in younger and older adults (Katz et al. 1989; Nelson et al. 1985, 1995; Young et al. 1988). Renal clearance of the hydroxy metabolites does decrease with age (Nelson et al. 1988a; Young et al. 1984). As a result, concentrations of hydroxynortriptyline may be substantially elevated in older patients.

In children, the clearance of tricyclic compounds is increased. Half-lives of imipramine are shorter and ratios of desmethylimipramine to imipramine are higher, consistent with more rapid metabolism

(Geller 1991; Rapoport and Potter 1981). Alternatively, a study of desipramine in children found that the clearance of both desipramine and hydroxydesipramine was increased so that hydroxy metabolite–parent compound ratios were not elevated (Wilens et al. 1992).

Relationship of Plasma Concentration to Clinical Action

Plasma Concentration and Response

Marked interindividual variability of tricyclic plasma concentrations was described by Hammer and Sjöqvist in 1967. This finding suggested that drug level monitoring might ensure that therapeutic blood levels are achieved and might help to avoid toxic levels. In carefully selected inpatients with endogenous or melancholic major depression, treatment with adequate levels of imipramine or desipramine resulted in robust response rates of about 85% (Glassman et al. 1977; Nelson et al. 1982). For several years, the relationship of tricyclic blood levels to response and the utility of monitoring blood levels were the focus of considerable attention and debate.

A task force of the American Psychiatric Association (1985) that reviewed these studies concluded that relationships between plasma level and response had been demonstrated for imipramine, desipramine, and nortriptyline (see Table 12–2). For imipramine, drug levels above 200 ng/mL were more effective than lower levels (Glassman et al. 1977; Reisby et al. 1977). For desipramine, levels above 125 ng/mL were more effective (Nelson et al. 1982). For both desipramine and imipramine, blood levels in excess of 300 ng/mL were more likely to be associated with serious side effects. Effective plasma concentrations were also established for nortriptyline, but the relationship appeared to be curvilinear. For this drug, plasma levels between 50 ng/mL and 150 ng/mL were more effective than lower or higher levels (Åsberg et al. 1971; Kragh-Sørenson et al. 1973, 1976).

For amitriptyline, it has been more difficult to establish a therapeutic relationship between plasma levels and response (American Psychiatric Association 1985). In part, this difficulty may be related to the fact that during amitriptyline administration, three active compounds are present (amitriptyline, nortriptyline, and hydroxynortriptyline), and it is unclear if their effects are additive or if there is a more complicated relationship (Breyer-Pfaff et al. 1982). During amitriptyline administration, responders usually have total amitriptyline and nortriptyline levels in the neighborhood of 150–250 ng/mL (Kupfer et al. 1977), but there is not good agreement between studies. For clomipramine, blood levels of 150–300 ng/mL (total of clomipramine and desmethylclomipramine) have been suggested for antidepressant effectiveness. Higher levels are usually employed in the treatment of OCD. The data relating blood levels and response are limited for the other tricyclic and tetracyclic compounds.

The therapeutic utility of blood level monitoring has been the subject of controversy. Blood level–response relationships have been demonstrated in melancholic inpatients. But similar relationships have proven difficult to demonstrate in depressed outpatients. In outpatients, drug–placebo differences are often small, and the effect of drug treatment is harder to detect. Depressed outpatients may be more heterogeneous and include individuals who are not responsive to any drug treatment. Finally, many studies are not designed to detect blood level–response relationships. Fixed dosing is required, and the plasma concentrations achieved must fall above and below the suspected threshold. If all patients achieve adequate drug concentrations, no relationship with response will be found. It is logical to conclude that blood level relationships determined in severely depressed inpatients might be used as a guide for treatment of outpatients, but this assumption has not been empirically validated.

Plasma Concentration and Toxicity

The alternative question is whether blood level monitoring might help to avoid toxicity. A variety of data support this view. The risk of delirium is substantially increased at amitriptyline plasma

concentrations above 450 ng/mL and is moderately increased at concentrations above 300 ng/mL (Livingston et al. 1983; Preskorn and Simpson 1982). But amitriptyline is the most anticholinergic tricyclic and is most likely to produce delirium. The risk of first-degree atrioventricular block is also increased with plasma concentrations of imipramine greater than 350 ng/mL (Preskorn and Irwin 1982). The risk of seizures also increases at higher doses and, presumably, higher blood levels, although a clear plasma-level threshold for seizures has not been demonstrated. Following overdose, tricyclic blood levels greater than 1,000 ng/mL can be achieved, and the risks of delirium, stupor, cardiac abnormalities, and seizures are all substantially increased (Preskorn and Irwin 1982; Rudorfer and Young 1980; Spiker et al. 1975).

The value of blood level monitoring to avoid serious adverse effects has been hard to demonstrate because rates of serious toxicity are low so that large samples are required to demonstrate any increase in risk at higher blood levels. For some adverse reactions (e.g., delirium), early warning signs may prompt dose reduction. Alternatively, there may be no warning for seizures or cardiac arrhythmia, and blood level monitoring might be most useful for reducing the risk of those adverse events.

If blood level monitoring is undertaken, the clinician needs to remember that the patient needs to be at steady state, the blood sample should be drawn before the next dose (a trough level), and the sample should be sent to the laboratory promptly. For a quantitative estimate the laboratory will usually employ high-performance liquid chromatography (HPLC). In a competent laboratory, the coefficient of variation for an HPLC assay is usually less than 10%. This assay is relatively specific; however, other drugs can interfere. Because there are many modifications of the HPLC technique, the interfering drugs will vary by site. Under the best of circumstances, there will still be biological variability of the compound (discussed earlier in subsection "Steady-State Concentrations"). Add to this occasional missed doses or laboratory problems, and there will be considerable sample-to-sample variability. For these reasons, the clinician should not view the concentration reported as a precise measure. Yet, because concentrations vary across such a wide range, it may be very helpful to know if the level is low (e.g., 25–75 ng/mL), moderate (e.g., 100–300 ng/mL), or high (e.g., 300–1,000 ng/mL).

Prospective Dosing Techniques

Conventional dosing requires administration of a given dose for a long enough period of time to determine whether that dose is effective. Sometimes two or three trials are needed to determine the effective dose. The possibility of rapid dosage adjustment using plasma levels was suggested when several investigators demonstrated a relationship between an initial timed blood sample and the final steady-state level (Alexanderson 1972; Brunswick et al. 1979; Cooper and Simpson 1978; Potter et al. 1980). This method appeared most applicable for nortriptyline, which has linear kinetics, but was also useful for desipramine, because the targeted level was within a broad range. Clinical studies using blood levels to adjust dose were reported for amitriptyline (Dawling et al. 1984; Madakasira and Khazanie 1985), but sedation and anticholinergic side effects limited the rate at which the dose could be adjusted. Alternatively, a clinical study using rapid dosing of desipramine found that treatment could be initiated at full dose once the dose needed to reach a therapeutic level was determined from a 24-hour blood level following a test dose (Nelson et al. 1987). Sixteen of the 18 patients who completed treatment had plasma levels within the targeted range, and side effects appeared to be no greater than those experienced with more gradual dosing.

The practical application of these methods was limited by laboratory issues. The laboratory performing the assay had to be prepared to determine drug concentrations accurately at very low levels (below the therapeutic range) and had to be able to report results quickly. Most labs were not prepared to do either. A more practical and clinically feasible method is to start the drug at a low or moderate fixed dose, obtain a blood sample after 5–7 days on that dose, and then make further adjustments based on

that level.

There are exceptions. Elderly depressed patients often require gradual dosing in order to assess tolerance. In panic patients, lower starting doses are employed to avoid exacerbation of panic attacks.

MECHANISM OF ACTION

Early biochemical theories of depression were in large part based on the knowledge of drug action. The observation that the tricyclic agents increased the availability of norepinephrine and serotonin suggested that depression resulted from a deficit in these neurotransmitters (Bunney and Davis 1965; Prange 1965; Schildkraut 1965). This work stimulated interest in the role of these neurotransmitters in the etiology of depression, and several abnormalities were identified. Yet, it remains unclear which, if any, of these abnormalities play a central role in causing depression or are responsible for the vulnerability to becoming depressed.

Recent challenge studies in depressed patients do confirm that the actions of antidepressant drugs are mediated by serotonin and norepinephrine. For example, administration of a tryptophan-free diet rapidly depletes serotonin and, in depressed patients who have been successfully treated, causes relapse (Delgado et al. 1990). In addition, tryptophan depletion caused relapse in patients who were treated with serotonergic agents, whereas those who were treated with norepinephrine reuptake inhibitors were relatively unaffected. Alternatively, administration of AMPT, which interrupts the synthesis of catecholamines, caused relapse in patients who were being successfully treated with noradrenergic agents but not those receiving serotonergic drugs (Delgado et al. 1993). Tryptophan depletion in untreated depressed patients, however, had no effect on the patients' depression. These studies provide supporting evidence that serotonin and norepinephrine mediate antidepressant effects, but they do not necessarily imply that alterations in these neurotransmitter systems are central to the pathophysiology of depression.

The synaptic effects of tricyclic and tetracyclic agents on norepinephrine and serotonin transporters and receptors were described in detail earlier (see section "Pharmacological Profile" earlier in this chapter).

The early theories of depression that focused on depletion of norepinephrine or serotonin suggested that it might be possible to identify "serotonergic" and "noradrenergic" depressions and that such identification would help the clinician select the appropriate type of antidepressant (Beckmann and Goodwin 1975; Maas et al. 1972). A number of studies investigated the predictive value of urinary MHPG, a metabolite of norepinephrine, but a definite predictive link with a noradrenergic antidepressant was not established. Some of these studies were, in part, hampered by the use of agents such as amitriptyline and imipramine, which are not very selective. However, even those studies that examined the ability of MHPG to predict response to more selective agents, such as zimelidine, fluoxetine, and desipramine, failed to demonstrate clear predictive utility (Bowden et al. 1993; Potter 1984). The data, taken together, suggest that urinary MHPG is not a clinically useful predictor. Nevertheless, these studies do not rule out the possibility that there are depressions in which serotonin or norepinephrine plays a relatively more prominent role.

More recently, research into the mechanism of action of the tricyclics and other antidepressant drugs has shifted to include consideration of factors affecting postsynaptic signal transduction (Manji et al. 1995). These factors include coupling of G proteins to the adrenergic receptor or to adenylyl cyclase and the activity of membrane phospholipases and protein kinases. Other novel targets, including glucocorticoid receptors (Barden 1996), neurotrophic factors (Duman et al. 1997), and gene expression (Lesch and Manji 1992; Nibuya et al. 1996; Schwaninger et al. 1995), have been explored.

INDICATIONS AND EFFICACY

Major Depression

The efficacy of the tricyclic and tetracyclic compounds in major depression is well established. The evidence for their effectiveness has been reviewed previously (Agency for Health Care Policy and Research 1993; Davis and Glassman 1989). Imipramine is the most extensively studied tricyclic antidepressant, in part because for many years it was the standard agent against which other new drugs were compared. In 30 of 44 placebo-controlled studies, imipramine was more effective than placebo. If data from these studies are combined, 65% of 1,334 patients *completing* treatment with imipramine were substantially improved, whereas 30% of those on placebo improved. *Intention-to-treat* response rates for placebo-controlled studies of imipramine in outpatients were 51% for imipramine and 30% for placebo (Agency for Health Care Policy and Research 1993). In most comparison studies, the other tricyclic and tetracyclic antidepressants have been found to be comparable to imipramine in efficacy.

The tricyclic compounds are also effective when used for maintenance treatment. Early studies demonstrated that maintenance treatment with a tricyclic would reduce the relapse rate associated with placebo by about 50% (Davis 1976). These studies, however, usually employed low doses. Subsequently, the Pittsburgh group found that imipramine, at full dose, effectively maintained nearly 80% of the depressed patients for a 3-year period compared with 10% of those on placebo (Frank et al. 1990). In this study, maintenance psychotherapy had an intermediate effect, with about 30% of the patients remaining well. Although this seminal study demonstrated the impressive value of maintenance treatment with full-dose imipramine, the magnitude of the findings may reflect characteristics of the sample treated. The sample comprised patients with recurrent depression who might have been expected to do poorly on placebo. In addition, the patients selected for the study had a history of symptom-free periods between prior episodes, suggesting that these patients might be more likely (than patients with a history of residual symptoms) to have a complete response to treatment. In practice, clinicians may encounter patients with chronic depression, patients with residual symptoms, or patients with comorbid medical and psychiatric disorders. For such patients, drug treatment may be more effective than placebo, but the actual number of patients whose depression remains in remission may be lower.

The U.S. Food and Drug Administration (FDA) has approved all of the tricyclic and tetracyclic compounds discussed in this chapter for the treatment of depression with the exception of clomipramine. In Europe, clomipramine is also used for depression; in fact, it is regarded by many as the most potent antidepressant.

Melancholia or Severe Depression

The efficacy of the tricyclic compounds appears to vary in different subtypes of depression. Four decades ago, when Kuhn studied imipramine, the prevailing view was that it was essential to establish efficacy of an antidepressant in patients with endogenous depression or at least in those with severe depression (Kuhn 1970). The early studies of imipramine and the other tricyclic compounds were frequently conducted in hospitalized patients with severe or endogenous depression, and in these patients the tricyclics were found to be effective. In fact, these agents may be especially effective in this group. Two studies of imipramine and desipramine found rates of response of about 85% in severely depressed hospitalized patients who did not have a refractory history, did not have prominent personality disorder, received an adequate plasma concentration of the drug, and completed treatment (Glassman et al. 1977; Nelson et al. 1982).

When the SSRIs were introduced, it was suggested that they might be less effective than the tricyclic antidepressants in treating severe or melancholic depression. In a large meta-analysis of more than 100 studies comparing tricyclic antidepressants and SSRIs, Anderson (2000) found that in general, these agents had comparable efficacy. When individual agents and patient characteristics were considered, the only tricyclic agent that appeared to be more effective than the SSRIs was amitriptyline, and the only patient characteristic was inpatient status. In a separate meta-analysis of

25 inpatient studies (Anderson 1998), the advantage of the tricyclics appeared limited to those with dual action, namely amitriptyline and clomipramine. Two of the most frequently cited studies in this regard were the two Danish University Antidepressant Group (1986, 1990) studies that found clomipramine to be more effective than paroxetine or citalopram in severely depressed inpatients. Recent clinical trials of antidepressants were usually conducted in outpatients with depression of moderate severity. In outpatients, the designation of melancholia does not appear to predict an advantage for tricyclic antidepressants versus SSRIs (Anderson and Tomenson 1994; Montgomery 1989). Although the question of the best treatment for severely melancholic inpatients lingers, the expense of these studies, and the shift in practice to treatment of depression in outpatient settings, has substantially decreased interest in this question.

Anxious Depression

Anxious depression is not recognized in DSM-IV-TR (American Psychiatric Association 2000) as a subtype of depression; nevertheless, it has been frequently studied. Three of the tricyclic and tetracyclic compounds—doxepin, amoxapine, and maprotiline—have received FDA approval for use in patients with depression and symptoms of anxiety. For many years, clinical lore suggested that amitriptyline was most effective for anxious depression. Direct comparison studies, however, have found little indication that one of these compounds is better than another for treatment of anxious depression. Depressed patients who are anxious may respond less well than less anxious patients. This has been observed with amitriptyline (Kupfer and Spiker 1981), imipramine (Roose et al. 1986), and desipramine (Nelson et al. 1994). Yet these drugs are still more effective than placebo in anxious depressed patients, and it is not established that other classes of antidepressants are more effective in these patients.

Atypical Depression

A series of studies by the Columbia University Group examined the efficacy of imipramine in depressed patients with atypical features (Liebowitz et al. 1984, 1988). These depressed patients had reactive mood and reversed vegetative symptoms, severe fatigue, or rejection sensitivity. Imipramine was more effective than placebo but significantly less effective than the monoamine oxidase inhibitor (MAOI) phenelzine. Other investigators have reported the value of switching from a tricyclic to an MAOI in tricyclic-refractory depressed patients, especially those with atypical features (McGrath et al. 1987; Thase et al. 1992). In fact, the validity and utility of the atypical subtype of depression were in large part supported by this observed difference. However, this subtype has not been shown to be preferentially responsive to SSRIs (Fava et al. 1997), nor has any second-generation antidepressant been shown to be superior to any other in treating atypical depression.

Psychotic Depression

In 1975, Glassman et al. observed that imipramine was less effective in patients with major depression who had delusions. Later, Chan et al. (1987), in reviewing several studies addressing this question and involving more than 1,000 patients, found that antidepressants—usually tricyclics—given alone were effective in approximately two-thirds of the nonpsychotic patients but only about one-third of those with psychotic features. Although the definition of psychosis has undergone several changes, currently it is defined in DSM-IV-TR as major depression with delusions or hallucinations. Several open studies reviewed elsewhere (Nelson 1987) and one prospective study (Spiker et al. 1985) found that the tricyclics, when combined with an antipsychotic, are effective in psychotic depression.

Anton and Burch (1990) suggested that because of its antipsychotic effects, amoxapine might be effective for psychotic depression. In a double-blind study, these researchers demonstrated that amoxapine was comparable in efficacy to the combination of perphenazine and amitriptyline in treating psychotic depression (Anton and Burch 1990).

Bipolar Depression

Thirty years ago, it was suggested that the MAOI antidepressants might be more effective than the tricyclics in treating bipolar depression (Himmelhoch et al. 1972). Later, Himmelhoch et al. (1991) demonstrated in a double-blind study that tranylcypromine was more effective than imipramine for bipolar depression. In addition, tricyclics are more likely than other agents to induce mania (Weir and Goodwin 1987). As a result, the tricyclics are not recommended for monotherapy of bipolar depression.

Chronic Major Depression and Dysthymia

Imipramine appears to be effective in treating chronic depression and dysthymia and to be relatively comparable to sertraline in efficacy (Keller et al. 1998; Kocsis et al. 1988; Thase et al. 1996). Imipramine and desipramine have both been studied in controlled trials and have been found to be more effective than placebo both for acute treatment and for maintenance treatment (N. L. Miller et al. 2001).

Late-Life Depression

Gerson et al. (1988) reviewed the studies of tricyclic antidepressants reported prior to 1986. They found 13 placebo-controlled trials but noted several problems, such as lack of diagnostic criteria, inclusion of younger patients, and dosing issues. Although tricyclics were effective, overall drug and placebo response rates in these older patients appeared to be lower than rates in nonelderly patients (Agency for Health Care Policy and Research 1993). Katz et al. (1990) performed one of the first placebo-controlled trials of nortriptyline in the treatment of patients older than 80 years living in a residential care facility. Nortriptyline was more effective than placebo. The doses employed and levels achieved were similar to those in younger subjects. This study remains the only study to date showing an advantage for an antidepressant over placebo in depressed patients older than 75 years.

Depression in Children

In children and adolescents, the tricyclic antidepressants have not demonstrated superiority over placebo (Ryan 1992).

Obsessive-Compulsive Disorder

Unlike depression, which responds to a variety of antidepressant agents, OCD appears to require treatment with a serotonergic agent. Clomipramine, the most serotonergic of the tricyclics, is approved by the FDA for use in OCD, and its efficacy in this disorder is well established (Greist et al. 1995). Studies comparing its effectiveness with noradrenergic agents such as desipramine found that clomipramine was substantially superior (Leonard et al. 1989). Although the SSRIs are effective in treating OCD, there is a suggestion that clomipramine may be superior (Greist et al. 1995). Whether this putative superiority is due to the dual mechanism of clomipramine or to other factors is unclear.

Panic Disorder

None of the tricyclic or tetracyclic drugs are approved for use in panic disorder. Yet imipramine was the first drug described for use in this disorder (Klein 1964). In fact, observation of the effects of imipramine helped to establish the diagnostic utility of panic disorder. The efficacy of both tertiary and secondary tricyclics has been demonstrated in controlled trials (Jobson et al. 1978; Munjack et al. 1988; Zitrin et al. 1980). In treating this disorder, the drug is initiated at a low dose to avoid exacerbation of panic symptoms.

Attention-Deficit/Hyperactivity Disorder

The efficacy of the stimulant drugs in treating attention-deficit/hyperactivity disorder (ADHD) is well established. The tricyclics, especially desipramine, also appear to be of value. In one study,

desipramine, given at doses greater than 4 mg/kg for 3–4 weeks, was effective in two-thirds of the children, whereas placebo was effective in only 10% (Biederman et al. 1989). Desipramine was also found to be more effective than placebo in adults with ADHD (Wilens et al. 1996). One of the advantages of desipramine is its low potential for abuse. Unfortunately, five cases of sudden death were reported in the early 1990s in children being treated with desipramine (Riddle et al. 1991, 1993). All were under the age of 12 years. As a result, desipramine is now contraindicated in children younger than 12 years (discussed in greater detail below; see section "Side Effects and Toxicology"). Given that tricyclics as a group share the same adverse cardiac effects, there is reason to be concerned that other tricyclics might also have safety issues in young children.

Pain Syndromes

The tricyclics and maprotiline have been widely used in various chronic pain syndromes. In a review of the literature, O'Malley et al. (1999) identified 56 controlled studies involving tricyclic antidepressant therapy for various pain syndromes, including headache (21 studies), fibromyalgia (18 studies), functional gastrointestinal syndromes (11 studies), idiopathic pain (8 studies), and tinnitus (2 studies), and Salerno et al. (2002) identified 7 more placebo-controlled trials of tricyclics or maprotiline used for chronic back pain. These agents were quite effective; in fact, the mean effect size (0.87) and the drug–placebo difference in response rates (32%) observed in pain syndromes are more robust than those usually observed in placebo-controlled studies in depression. In studies in which depression was also assessed, improvement in pain appeared to be independent of improvement in depression. Thus, the analgesic effects of these compounds were not simply the result of their antidepressant effects.

The mechanism of these agents' analgesic effects appears to differ from that of their antidepressant effects. The antinociceptive actions of the antidepressants result from actions on descending norepinephrine and serotonin pathways in the spinal cord (Yoshimura and Furue 2006). In animals, norepinephrine reuptake inhibitors and combined norepinephrine–serotonin reuptake inhibitors appear to be more potent than SSRIs (Mochizucki 2004). In humans, there is some evidence that the combined-action agents amitriptyline and clomipramine are more effective than the SSRI fluoxetine (Max et al. 1992) or the norepinephrine-selective agents maprotiline (Eberhard et al. 1988) and nortriptyline (Panerai et al. 1990). In humans, antidepressant dosing and timing of effects for pain differ from those observed in depression. For example, usual dosages of amitriptyline required for pain management ($\leq$75 mg/day) are lower than those required to treat depression (15–300 mg/day), and response occurs more quickly, usually within the first 1 or 2 weeks.

Other Indications

Imipramine has been used for treatment of nocturnal enuresis in children with FDA approval, and controlled trials indicate that it is clearly effective (Rapoport et al. 1980). The dose of imipramine is usually 25–50 mg at bedtime. Amitriptyline and nortriptyline also appear to be useful, although they are not approved for use in this disorder. The mechanism of action is unclear but may in part be anticholinergic. It is not clear, however, that the risk of cardiac problems would be substantially less with tricyclics other than desipramine in children younger than 12 years, although the low doses required may reduce this risk.

Tricyclic antidepressant drugs have been extensively studied in patients with schizophrenia. However, in the absence of a major depressive syndrome, these agents appear to be of limited value (Siris et al. 1978).

SIDE EFFECTS AND TOXICOLOGY

The delineation of side effects during the treatment of depressed patients is complicated because depression itself is accompanied by a variety of somatic symptoms. For example, headache,

constipation, and drowsiness—symptoms usually considered as "side effects"—have been observed in more than 50% of untreated inpatients with major depression if these symptoms were each directly assessed (Nelson et al. 1984). During treatment, patients may be quick to label these somatic symptoms as side effects even if the symptoms were preexisting. Another manifestation of this issue is the rate of spontaneously reported "side effects" on placebo in clinical trials. One of the best examples is headache. Clinical trial data for recently marketed antidepressants indicate that the rate of headaches on placebo in depressed outpatients ranges from 17% to 24% (Physicians' Desk Reference 2002). For fluoxetine, sertraline, paroxetine, and bupropion, the rate for drug was only 1%–2% higher than that for placebo. For venlafaxine XR and citalopram, the rate of headaches was higher for placebo than for drug. A strong argument can be made that headache is usually a symptom of depression. Of course, these mean values conceal the possibility that a symptom may worsen or emerge during treatment in some patients and improve with treatment in others. In groups of patients, however, the strongest predictor of overall somatic symptom severity is the severity of the depression at the time of assessment (Nelson et al. 1984), and the best intervention may be more aggressive treatment.

Another general factor contributing to side effects is the patient's vulnerability. For example, one of the best predictors of orthostatic hypotension during treatment is the presence of orthostatic hypotension prior to treatment (Glassman et al. 1979). Seizures are most likely in a patient with a history of seizures (Rosenstein et al. 1993). Cardiac conduction problems are most likely to occur in patients with preexisting conduction delay (Roose et al. 1987a).

The final manifestation of somatic symptoms during treatment is the net result of the interaction of direct effects of the medication on specific organs, the indirect effects of the medication on depression and its associated somatic symptoms, and the patient's vulnerability to certain symptoms. The attribution of cause—that is, whether a physical symptom is a "side effect" of a drug or a symptom of depression—involves a judgment about whether the symptom is new or has worsened during drug treatment.

Antidepressant drugs do, of course, have direct effects on a variety of organs and can produce adverse effects. The in vitro potency or affinity of antidepressant compounds for various receptor sites (see Table 12–1) is one method for comparing the likelihood that various agents will produce specific side effects. A related issue is how the in vitro potency of a secondary effect relates to the potency of the primary action of the drug. If the secondary effect is more potent, it will occur at concentrations below the therapeutic level of the drug. An example for the tricyclics is orthostatic hypotension, which often manifests at plasma concentrations below the usual antidepressant threshold. Alternatively, in patients without preexisting medical illness, the proarrhythmic and proconvulsant effects of the tricyclic antidepressants are uncommon at therapeutic concentrations but become more frequent at levels encountered in overdose.

Central Nervous System Effects

The principal action of the tricyclic and tetracyclic agents in the central nervous system is to alleviate depression. In particular, they reduce the symptoms of depression rather than simply elevating mood. Nondepressed subjects given imipramine may feel sleepy, quieter, light-headed, clumsy, and tired. These effects are generally unpleasant (DiMascio et al. 1964).

The anticholinergic and antihistaminic effects of the tricyclics and tetracyclics can produce confusion or delirium. The incidence of delirium is dose-dependent and increases at blood levels above 300 ng/mL. One study reported that 67% of patients with blood levels above 450 ng/mL developed delirium when receiving the tertiary amines, particularly amitriptyline (Livingston et al. 1983; Preskorn and Simpson 1982). The clinician should be alert to the possibility of delirium in a patient whose depression is worsening during treatment. This can be especially problematic in patients with

psychotic depression. Patients with concurrent dementia are particularly vulnerable to the development of delirium, and the more anticholinergic tricyclics should be avoided in these patients. Intramuscular or intravenous physostigmine can be used to reverse or reduce the symptoms of delirium. Although physostigmine may represent a useful diagnostic test, its short duration of action makes the continued use of this agent difficult.

Seizures can occur with all of the tricyclic and tetracyclic agents and are dosage- and blood level–related (Rosenstein et al. 1993). For clomipramine, the risk for seizures is reported to be 0.5% at dosages up to 250 mg/day. At dosages above 250 mg/day, the seizure risk increases to 1.67% (new drug application data on file with the FDA). For maprotiline, the overall risk of seizures is reported to be 0.4%, but, again, this risk increases at dosages above the maximum recommended dose of 225 mg/day (Dessain et al. 1986). The seizure risk for some of the older compounds was not as well established at the time of marketing. A retrospective meta-analysis of imipramine found an estimated seizure rate of 1 per 1,000 patients receiving less than 200 mg/day (Peck et al. 1983). At dosages above 200 mg/day, the rate was 0.6%. Another large review (Jick et al. 1983) found similar dose-dependent rates for amitriptyline and doxepin. Rates of 1%–4% have been reported at doses between 250 mg/day and 450 mg/day, but the samples in these studies were often small, and the confidence intervals for these rates were large. Consistent with a dose-dependent effect, the risk of seizures is substantially increased following overdose (Spiker et al. 1975). Seizure rates for the secondary amines have not been well described. Because the risk of convulsions is clearly increased in patients with predisposing factors such as a prior history of seizures, brain injury, or presence of neuroleptics; because the rates are low (e.g., 1/100); and because sample size in drug trials is often on the order of 200 patients, inclusion of a few patients who have a significant vulnerability to seizures can have a marked effect on the rate of seizures reported. The mechanism by which tricyclics produce seizures is not well understood. It has been suggested that antidepressant drugs induce convulsions by acting at the γ-aminobutyric acid (GABA) receptor chloride–ionophore complex, where they inhibit chloride conductance (Escorihuela et al. 1989; Malatynska et al. 1988).

A fine, rapid tremor can occur with use of tricyclic agents. Because this tremor is dose dependent, tends to occur at higher levels, and is not a typical depressive symptom, development of a tremor may be a clinical indicator of an elevated blood level (Nelson et al. 1984). Dose reduction will often lead to improvement in the tremor.

Because the 7-hydroxy metabolite of amoxapine has neuroleptic properties, administration of amoxapine carries the potential risk of neuroleptic malignant syndrome, which has been reported (Lesaca 1987; Madakasira 1989; Taylor and Schwartz 1988; Washington et al. 1989), and tardive dyskinesia. The occurrence of these adverse events is rare; however, the seriousness of the risk and the availability of many alternatives suggest that use of amoxapine should be reserved for patients whose clinical condition warrants the use of an agent with antipsychotic properties.

Anticholinergic Effects

The tricyclics block muscarinic receptors and can cause a variety of anticholinergic side effects, such as dry mouth, constipation, blurred vision, and urinary hesitancy. These effects can precipitate an ocular crisis in patients with narrow-angle glaucoma. The tricyclic and tetracyclic compounds vary substantially in their muscarinic potency (see Table 12–1). Amitriptyline is the most potent, followed by clomipramine. Of the tricyclics, desipramine is the least anticholinergic. Amoxapine and maprotiline also have minimal anticholinergic effects. Anticholinergic effects can contribute to tachycardia, but tachycardia also occurs as a result of stimulation of β-adrenergic receptors in the heart. Thus, tachycardia regularly occurs in patients receiving desipramine, which is minimally anticholinergic (Rosenstein and Nelson 1991).

Although anticholinergic effects may be annoying, they are usually not serious. They can, however,

become severe. An ocular crisis in patients with narrow-angle glaucoma is an acute condition associated with severe pain. Urinary retention can be associated with stretch injuries to the bladder. Constipation can progress to severe obstipation. (Paralytic ileus has been described but is rare.) In these conditions, medication must be discontinued and appropriate supportive measures instituted. Elderly patients are at greatest risk for severe adverse consequences. The frequency of severe anticholinergic adverse reactions is increased by concomitant neuroleptic administration. Use of nortriptyline or desipramine, either of which is less anticholinergic, can help to reduce the likelihood of these problems.

Anticholinergic effects may benefit from other interventions. Bethanechol (Urecholine) at a dosage of 25 mg three or four times a day may be helpful in patients with urinary hesitancy. The regular use of stool softeners helps to manage constipation. Patients with narrow-angle glaucoma who are receiving pilocarpine eyedrops regularly can be treated with a tricyclic, as can those who have had an iridectomy. Tricyclic agents do not affect patients with chronic open-angle glaucoma.

Antihistaminic Effects

Several of the tricyclic compounds and maprotiline have clinically significant antihistaminic effects. Doxepin is the most potent H_1 receptor blocker in this group. It is more potent than the commonly administered antihistamine diphenhydramine. More recently, however, it has been surpassed by mirtazapine and olanzapine, which are even more potent antihistamines. Central H_1 receptor blockade can contribute to sedation and delirium and also appears to be related to the increased appetite and associated weight gain that patients may develop with chronic treatment. Because of their sedating effects, the tricyclic antidepressants, especially amitriptyline, have been used as hypnotics. Given their cardiac effects and the frequency of lethal overdose, this practice should be discouraged.

Cardiovascular Effects

Orthostatic hypotension is one of the most common reasons for discontinuation of tricyclic antidepressant treatment (Glassman et al. 1979). It can occur with all of the tricyclics but appears to be less pronounced with nortriptyline (Roose et al. 1981; Thayssen et al. 1981). The α_1-adrenergic blockade associated with the tricyclics contributes to orthostatic hypotension; however, it is the postural reflex that is primarily affected. Resting supine blood pressure may be unaffected or can even be elevated (Walsh et al. 1992). Orthostatic hypotension is most likely to occur or is most severe in patients who have preexisting orthostatic hypotension (Glassman et al. 1979). It is also aggravated by concurrent antihypertensive medications, especially volume-depleting diuretic agents. The elderly are more likely to have preexisting hypotension and are also more vulnerable to the consequences of orthostatic hypotension, such as falls and hip fractures.

Often, orthostatic hypotension occurs at low blood levels, so that dosage reduction is not a helpful management strategy. Gradual dose adjustment may allow accommodation to the subjective experience of light-headedness, but the actual orthostatic blood pressure changes do not accommodate within a reasonable period of time (e.g., 4 weeks) (Roose et al. 1998). Thus, unless the plasma level is elevated and the dose can be reduced, patients who experience serious symptomatic orthostatic hypotension may not be treatable with a tricyclic antidepressant. Fludrocortisone (Florinef) has been used to raise blood pressure, but in this author's experience it is not very effective. If patients are receiving antihypertensives, it may be possible and helpful to reduce the dose of these agents.

Desipramine has been reported to raise supine blood pressure in younger patients, although it is not clear this effect is limited to that age group (Walsh et al. 1992). This effect may be similar to that reported for venlafaxine.

Tachycardia occurs with all the tricyclics, not just the more anticholinergic agents. Both supine and

postural pulse changes can occur, and the standing pulse can be markedly elevated. A relatively recent study of nortriptyline, dosed to a therapeutic plasma concentration, found a mean pulse rise of 11% (8 beats per minute) (Roose et al. 1998). Patients do not accommodate to the pulse rise, which can persist for months. Tachycardia is more prominent in younger patients, who appear more sensitive to sympathomimetic effects, and is one of the most common reasons for drug discontinuation in adolescents. A persistent pulse rise in older patients, however, increases cardiac work and may be clinically significant in patients with ischemic heart disease.

The effect of tricyclic antidepressants on cardiac conduction has been a subject of great interest. Cardiac arrhythmia is the principal cause of death following overdose (Biggs et al. 1977; Pimentel and Trommer 1994; Spiker et al. 1975). As a result of this observation, for many years there was great concern about the use of tricyclic antidepressants in patients with and without heart disease. The effect of these agents has now been well described. Apparently, through inhibition of Na^+/K^+-ATPase, the tricyclics stabilize electrically excitable membranes and delay conduction, particularly His ventricular conduction. Consequently, the tricyclics have type I antiarrhythmic qualities or quinidine-like effects.

At therapeutic blood levels, the tricyclics can have beneficial effects on ventricular excitability. In patients with preexisting conduction delay, however, the tricyclic antidepressants can further delay conduction and cause heart block (Glassman and Bigger 1981; Roose et al. 1987b). A pretreatment QTc interval of 450 milliseconds or greater indicates that conduction is already delayed, that a tricyclic may aggravate this condition, and that the patient is not a candidate for tricyclic antidepressant treatment. High drug plasma levels further increase the risk of cardiac toxicity. For example, first-degree atrioventricular heart block is increased with imipramine plasma concentrations above 350 ng/mL (Preskorn and Irwin 1982).

The tricyclic antidepressants do not reduce cardiac contractility or cardiac output (Hartling et al. 1987; Roose et al. 1987a). Studies using radionuclide angiography indicate no adverse effect of imipramine or doxepin on cardiac output, even in patients with diminished left ventricular ejection fractions. But orthostatic hypotension was common in these studies and could be severe in these patients.

Glassman et al. (1993), noting that the type I antiarrhythmic drugs given following myocardial infarction actually increased the risk of sudden death, suggested that the tricyclics may pose similar risks. The risk of sudden death is also increased when heart rate variability is reduced, and the tricyclics reduce heart rate variability (Roose et al. 1998).

As mentioned earlier (see subsection "Attention-Deficit/Hyperactivity Disorder"), sudden death has been reported in five children under the age of 12 years who were receiving desipramine (Riddle et al. 1991, 1993). It was suggested that the immature conduction system in some children might render them more vulnerable to the cardiac effects of desipramine. Subsequently, a study was conducted in 71 children with 24-hour cardiac monitoring (Biederman et al. 1993). No cardiac abnormalities were observed. Wilens et al. (1992) examined the possibility that hydroxydesipramine might reach unusually high levels in children and adolescents, but such levels were not found. A study of electrocardiographic parameters in that sample failed to show a relationship between those parameters and concentrations of desipramine or hydroxydesipramine (Wilens et al. 1993). Although these studies failed to reveal a mechanism for the sudden deaths reported, they do suggest that these events are not predictable, that they are not dose-dependent cardiac effects, and that usual blood level or electrocardiogram monitoring is not likely to identify those at risk.

To summarize the clinical implications of these cardiac effects, the clinician may wish to consider the following. In adults without cardiac disease, orthostatic hypotension may occur with tricyclic use, but conduction problems are not likely. In patients with preexisting conduction delay, the tricyclics may cause heart block. In patients with ischemic heart disease, continued use of tricyclics will increase

cardiac work and reduce heart rate variability, possibly increasing the risk of sudden death. Children younger than 12 years also appear vulnerable to the risk of sudden death during tricyclic administration, possibly because of cardiac conduction effects or reduced heart rate variability. Cardiac arrhythmia is the most common cause of death with tricyclic overdose. These cardiac safety issues, coupled with the recently reported safety of the SSRI sertraline when administered for depression following myocardial infarction (Glassman et al. 2002), indicate that the tricyclics are relatively contraindicated in patients with ischemic heart disease and that their use should be reserved for patients whose illnesses are refractory to other treatments.

Hepatic Effects

Acute hepatitis has been associated with administration of imipramine (Horst et al. 1980; Moskovitz et al. 1982; Weaver et al. 1977) and desipramine (Powell et al. 1968; Price and Nelson 1983). Mild increases of liver enzymes (less than three times normal) are not uncommon and usually can be monitored safely over a period of days or weeks without apparent harmful consequences. These changes in liver enzymes do not appear to be related to drug concentrations (Price et al. 1984). Acute hepatitis is relatively uncommon but can occur. The etiology is not well established but in some cases appears to be a hypersensitivity reaction. It is characterized by very high enzyme levels (e.g., aspartate aminotransferase [AST] levels >800), which develop within days. The enzyme pattern can be either hepatocellular or cholestatic. Enzyme changes may precede clinical symptoms, especially in the hepatocellular form. If a random blood test indicates mildly elevated liver enzymes, enzyme levels can be followed for a few days. Because of the rapid rise in liver enzyme levels in acute hepatitis, that condition will become evident quickly and will be easily distinguished from mild, persistent enzyme level elevations.

Acute hepatitis is a dangerous and potentially fatal condition. The antidepressant must be discontinued and should not be introduced again because the next reaction may be more severe. Unfortunately, it is not uncommon for the patient to be receiving several medications, so that the offending agent may be hard to identify. The risk of severe drug-induced hepatitis is not well established. This author has observed four cases associated with desipramine in the course of treating approximately 500 patients.

Other Side Effects

Increased sweating can occur with the tricyclic compounds and occasionally can be marked. The mechanism for this symptom is unclear but may be associated with noradrenergic effects. Another side effect for which the mechanism is unclear is carbohydrate craving. This effect, when coupled with antihistaminic effects, can lead to significant weight gain. One report of outpatients treated with amitriptyline found an average gain of 7 kg during a 6-month period (Berken et al. 1984). Weight gain appears to be greater with the tertiary compounds (Fernstrom et al. 1986) and is less common with nortriptyline, desipramine, and protriptyline. Sexual dysfunction has been described with the tricyclics but generally is less common with this group than during treatment with the SSRIs. This side effect appears to be associated with the more serotonergic compounds and does occur with clomipramine. Tricyclic antidepressants can cause allergic skin rashes, which are sometimes associated with photosensitivity reactions. Various blood dyscrasias also have been reported; fortunately, these are very rare.

Overdose

Because antidepressants are used for depressed patients who are at risk for overdose, the lethality of antidepressant drugs in overdose is of great concern. A tricyclic overdose of 10 times the total daily dose can be fatal (Gram 1990; Rudorfer and Robins 1982). Death most commonly occurs as a result of cardiac arrhythmia. However, seizures and central nervous system depression can occur. Although the use of tricyclics for the treatment of depression has declined, amitriptyline remains widely used for

other disorders, such as pain.

The total number of deaths associated with amitriptyline is comparable to that for all other tricyclics and tetracyclics combined. Overdoses often include multiple drugs. In 2006, the American Association of Poison Control Centers (Bronstein et al. 2007) began reporting deaths based on single substance ingestions, which gives a more accurate estimate of lethality. There were 2,730 ingestions of amitriptyline, with 6 deaths, and 1,938 ingestions of all other tricyclic and tetracyclic antidepressants, with 6 deaths. By comparison, there were 19,598 ingestions of various SSRIs, with 3 deaths. The mortality rate for the cyclic antidepressants was 257 per 100,000, while the rate for the SSRIs was 15.3 per 100,000, a 17-fold difference. All of the tricyclic and tetracyclic compounds are dangerous in overdose. Desipramine appears to have a particularly high fatality rate. Amoxapine has been reported to produce high rates of seizure in overdose. But the differences among these drugs are relatively minor in comparison with the improved safety of the second-generation antidepressant agents.

Teratogenicity

Although it would be ideal to discontinue all drugs during pregnancy, the patient and physician are faced with a dilemma. The risk of relapse is a serious concern in patients with recurrent depression because the risk may be increased during pregnancy or the postpartum period. This risk is particularly high for patients with a prior history of depression during or following pregnancy. The long history of tricyclic use without observation of birth defects argues for the safety of these agents. Of course, the patient must be informed of the possible risks and benefits of taking the drug and of discontinuing treatment before making a decision.

If tricyclics are continued during pregnancy, dosage adjustment may be required because of metabolic changes related to the pregnancy (Altshuler and Hendrick 1996). Drug withdrawal following delivery can occur in the infant and is characterized by tachypnea, cyanosis, irritability, and poor sucking reflex. The drugs in this class should be discontinued 1 week prior to delivery if possible. The tricyclics are excreted in breast milk at concentrations similar to those in plasma. The actual quantity delivered, however, is very small, so that drug levels in the infant are usually undetectable (Rudorfer and Potter 1997).

DRUG–DRUG INTERACTIONS

Pharmacodynamic Interactions

Pharmacodynamic interactions are those in which the action of one drug affects the action of the other. More commonly, the effects of the two drugs are additive and result in an adverse event. Perhaps the best example is the interaction of the tricyclics with MAOI drugs. The most dangerous sequence is to give a large dose of a tricyclic to a patient who is already taking an MAOI. This can result in a sudden increase in catecholamines and a potentially fatal hypertensive reaction. These two compounds have been used together to treat patients with refractory depression (Goldberg and Thornton 1978; Schuckit et al. 1971). Treatment is begun with lower doses, and either the two compounds are started together or the tricyclic is started first. Once begun, coadministration may actually reduce the risk of tyramine reactions (Pare et al. 1985); however, because the protective effect is variable and unpredictable, the usual MAOI diet is maintained.

Perhaps the most common pharmacodynamic interaction is when two psychotropic drugs are added together, resulting in increased sedation. This interaction might occur when tricyclics are combined with antipsychotic agents or with benzodiazepines. Other pharmacodynamic interactions can occur. By blocking the transporters, the tricyclics block the uptake and thus interfere with the action of guanethidine. Desipramine and the other tricyclics reduce the effect of clonidine.

Quinidine is an example of a drug with a potential dynamic and kinetic interaction with tricyclics. Because the tricyclics have quinidine-like effects, the effects of tricyclics and quinidine on cardiac

conduction are potentially additive. In addition, quinidine is a potent CYP2D6 isoenzyme inhibitor that can raise tricyclic levels, further adding to the problem.

Pharmacokinetic Interactions

Recently, pharmacokinetic interactions have received considerable attention. One type of pharmacokinetic interaction is enzyme inhibition. A number of drugs can block the metabolic pathways of the tricyclics, resulting in higher and potentially toxic levels. Desipramine has been of particular interest because its metabolism is fairly simple, occurring via the CYP2D6 isoenzyme. Because there are no major alternative pathways, inhibition of CYP2D6 can result in very high desipramine plasma levels, and toxicity can occur (Preskorn et al. 1990). A number of drugs inhibit 2D6. Quinidine, mentioned above, is a very potent 2D6 inhibitor. Other drugs commonly used in psychiatry that inhibit CYP2D6 include the SSRIs fluoxetine and paroxetine, duloxetine, bupropion, and some antipsychotics. Fluoxetine and paroxetine at usual doses raise desipramine levels, on average, three- to fourfold in extensive metabolizers (Preskorn et al. 1994). In slow metabolizers, enzyme inhibitors have less of an effect, because the patients are already deficient in the enzyme and the drug level is already high. In ultrarapid metabolizers, fluoxetine and paroxetine may cause a greater increase in desipramine levels, but these patients are likely to have very low initial desipramine levels. Sertraline 50 mg/day increases desipramine levels, on average, about 30%–40%, which is not a clinically meaningful difference (Preskorn et al. 1994). At higher doses, there is proportionally greater inhibition, but the increase is still substantially less than the 300%–400% increase that occurs with fluoxetine or paroxetine. The magnitude of the effect of bupropion on CYP2D6 has not been reported but appears to be clinically significant. Venlafaxine, nefazodone, mirtazapine, and citalopram appear to have minimal effects on 2D6. 2D6 inhibitors would be expected to block nortriptyline metabolism, but the magnitude of this interaction has not been well studied.

Antipsychotic agents such as chlorpromazine and perphenazine also inhibit 2D6 (Gram et al. 1974; Nelson and Jatlow 1980). At usual doses, perphenazine raises desipramine levels, on average, twofold, but this effect varies with dose and with the neuroleptic employed. Haloperidol can also inhibit the CYP2D6 pathway, but in this author's experience, this effect is not likely to be clinically meaningful at low dosages (e.g., <10 mg/day).

Because the tertiary tricyclics are metabolized by several pathways (CYP1A2, 3A4, 2C19), a selective inhibitor of one pathway would be likely to have less of an effect on these compounds. Drug interactions with the tertiary amines do occur but appear to be less robust. Methylphenidate appears to inhibit demethylation of imipramine to desipramine. At this point, numerous drug interactions have been described, although many are of doubtful clinical significance (for comprehensive reviews, see Nemeroff et al. 1996; Pollock 1997).

The other type of pharmacokinetic drug interaction is enzyme induction. The result of this interaction may render the drug acted upon ineffective. Unlike enzyme inhibition, which occurs quickly, enzyme induction requires synthesis of new enzyme. As a result, the full effect of an enzyme inducer may take 2–3 weeks to develop. If the inducer is discontinued, the effect takes 2–3 weeks to dissipate. Barbiturates and carbamazepine are potent inducers of CYP3A4. Phenytoin also can induce this enzyme, but its effects on the tricyclics appear to be less dramatic. Although CYP2D6 is a noninducible isoenzyme, phenobarbital reduces the availability of desipramine substantially. Apparently when CYP3A4 is induced, it becomes an important metabolic pathway for desipramine and the other tricyclics. In this author's experience, it can be difficult to attain an effective blood level of desipramine in the presence of a barbiturate.

Nicotine induces the CYP1A2 pathway and may lower concentrations of the tertiary tricyclics, but the secondary tricyclics (e.g., desipramine, nortriptyline) appear to be less affected.

Alcohol has a complicated interaction with the tricyclics. Acute ingestion of alcohol can reduce

first-pass metabolism, resulting in higher tricyclic levels. Because tricyclic overdose is often associated with alcohol ingestion, this is an important interaction, resulting in higher tricyclic levels. Alternatively, chronic use of alcohol appears to induce hepatic isoenzymes and may lower tricyclic levels (Shoaf and Linnoila 1991).

The tricyclics themselves produce some enzyme inhibition, but few clinically significant interactions have been described. The tertiary tricyclics compete with warfarin for some metabolic enzymes (e.g., CYP1A2) and may raise warfarin levels.

CONCLUSION

The tricyclic drugs were the mainstay of treatment for depression for three decades. Although the second-generation antidepressants appear to be better tolerated, no new agent has been shown to be more effective than the tricyclics, and if anything, there has been concern that the new agents may be less effective. The tricyclics were "dirty" drugs; that is, they had multiple actions. Although their side effects have been emphasized, these multiple actions may have contributed to their efficacy. Not only does amitriptyline block uptake of 5-HT, but its metabolite blocks uptake of norepinephrine, and in addition, amitriptyline is a 5-HT_2 antagonist. The principal drawback of this class of agents is the risk of serious cardiac adverse effects. They can aggravate arrhythmia in patients with preexisting conduction delay. They also may increase the risk of sudden death in children and in patients with ischemic heart disease. Moreover, a week's supply of medication taken in overdose could be fatal. As noted, even though the use of the tricyclics has diminished, amitriptyline remains a common cause of death by overdose in the United States. Because of these adverse effects, it is unlikely that there will be a resurgence of interest in the tricyclics. Nevertheless, the efficacy of these agents across a range of disorders, including pain, suggests the possible advantage of antidepressant drugs with multiple actions.

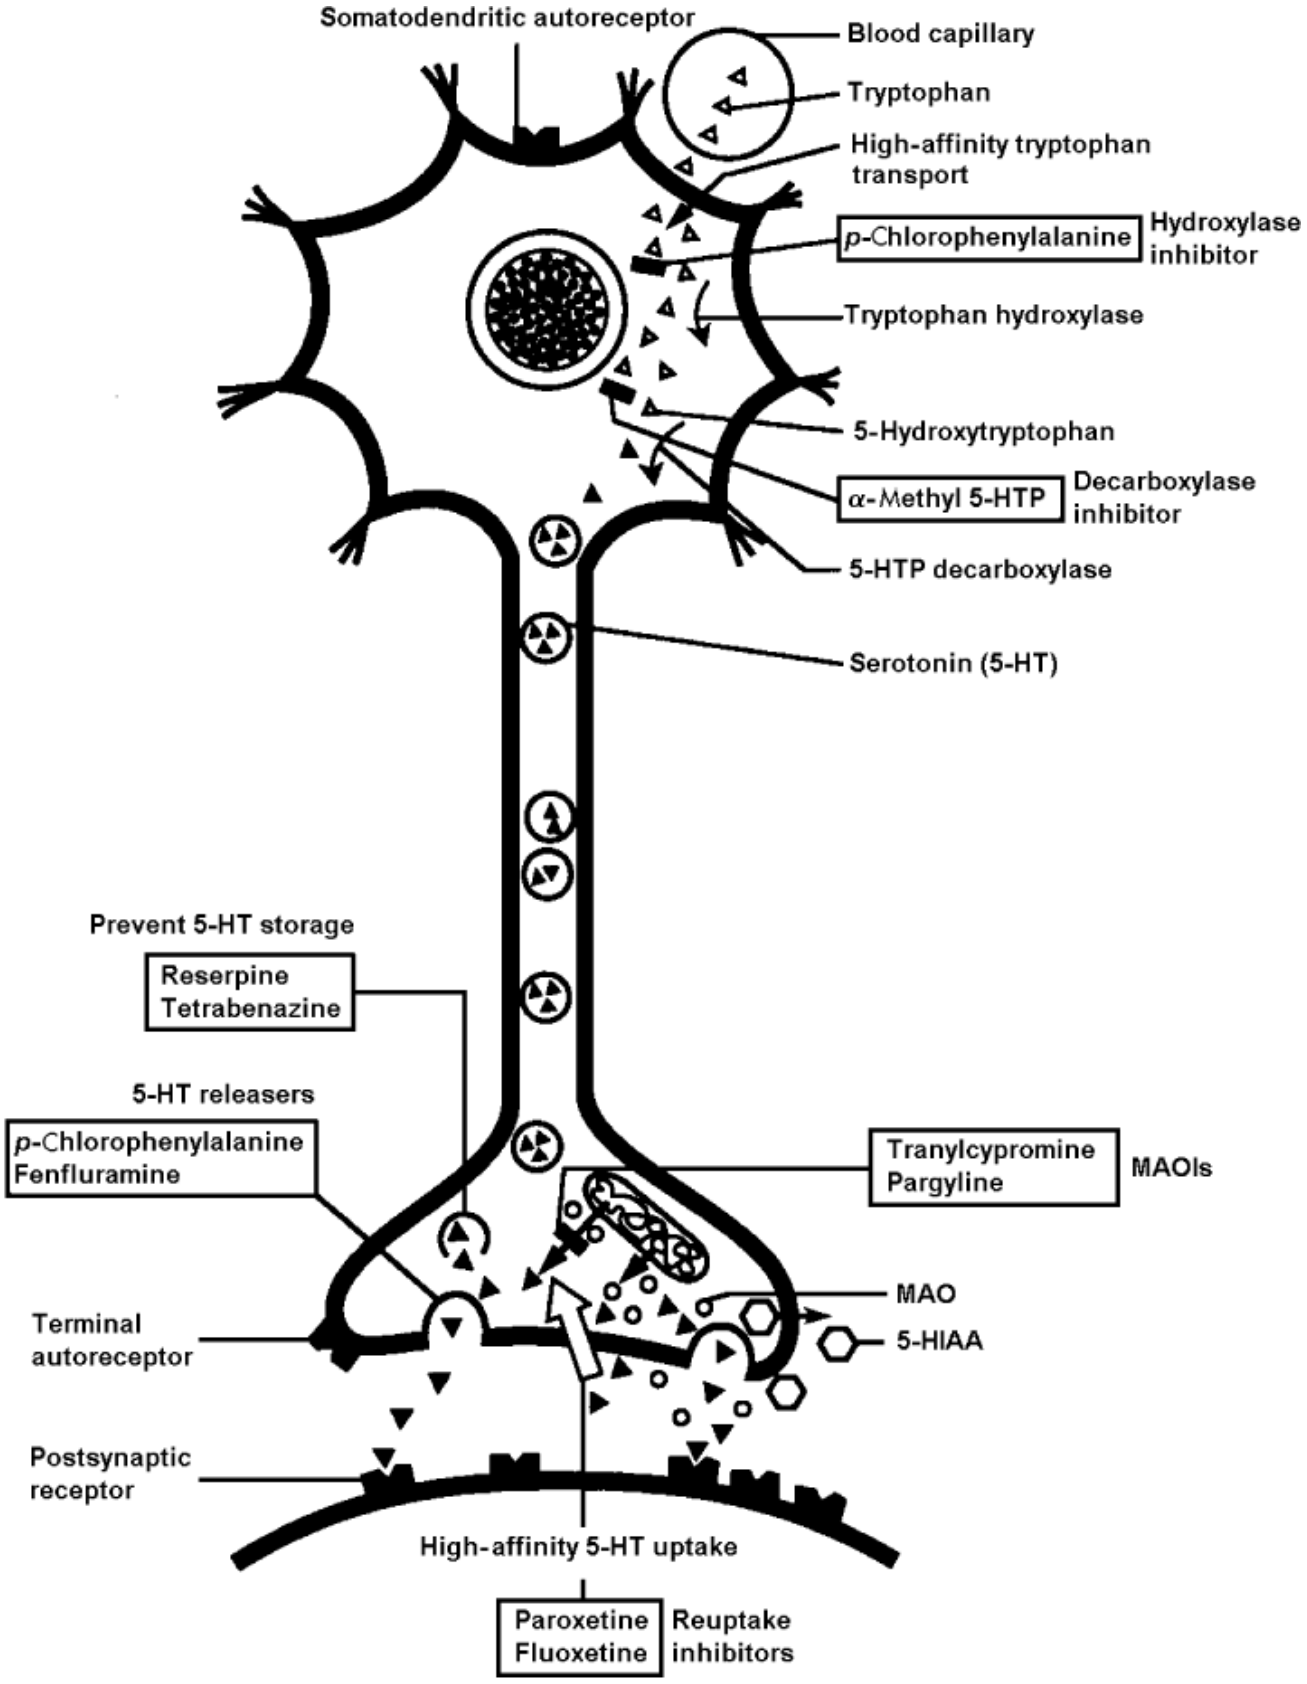
Chapter 13. Fluoxetine

FLUOXETINE: INTRODUCTION



The introduction of fluoxetine as the first selective serotonin reuptake inhibitor (SSRI) approved in the United States, initially for the treatment of depression, represents an important advance in psychopharmacology and has been the catalyst for much subsequent basic and clinical research. Considerable evidence has demonstrated that fluoxetine, like other SSRIs, has a broad spectrum of clinical indications. There is a consensus, however, that the commercial success of fluoxetine (and subsequently marketed SSRIs) derived from its advantageous safety profile, which propelled SSRIs to dominance in the antidepressant drug market. Fluoxetine, under the brand name Prozac, became a cultural icon—a symbol of the growth in antidepressant prescribing and depression recognition. Consequently, it also became a focus of controversies about rare events attributed to side effects, such as violent acts and suicide, and a symbol of the medicalization of mental health concerns. Fluoxetine was also the first of the SSRI blockbuster drugs to become available in generic form; ironically, with decreased cost has come decreased market share, likely reflecting the reduction in marketing and availability of office samples. Although SSRIs, as a class, share several common features, individual agents, such as fluoxetine, also have unique characteristics.

HISTORY AND DISCOVERY

Serotonin (5-HT) is an indoleamine with wide distribution in plants, animals, and humans. Pioneering histochemistry by Falck et al. (1962) found that 5-HT was localized within specific neuronal pathways and cell bodies. These originate principally from two discrete nuclei, the medial and dorsal raphe. Across animal species, 5-HT innervation is widespread. Although regional variations exist, several limbic structures manifest especially high levels of 5-HT (A. H. Amin et al. 1954).

However, 5-HT levels in the central nervous system (CNS) represent only a small fraction of 5-HT found in the body (Bradley 1989). Because 5-HT does not cross the blood–brain barrier, it must be synthesized locally. 5-HT is released into the synapse from the cytoplasmic and vesicular reservoirs (Elks et al. 1979). Following release, 5-HT is principally inactivated by reuptake into nerve terminals through a sodium/potassium (Na^+/K^+) adenosine triphosphatase (ATPase)–dependent carrier (Shaskan and Snyder 1970). The transmitter is subsequently subject to either degradation by monoamine oxidase (MAO) or vesicular restorage. Abnormalities in central 5-HT function have been hypothesized to underlie disturbances in mood, anxiety, satiety, cognition, aggression, and sexual drives, to highlight a few. As described by Fuller (1985), there are several loci at which therapeutic drugs might alter 5-HT neurotransmission (Figure 13–1). The explosion of knowledge regarding the serotonergic system can largely be traced to the development of compounds, such as fluoxetine, that block the reuptake of this neurotransmitter.

STRUCTURE–ACTIVITY RELATIONS

Drugs that inhibit 5-HT reuptake vary in their selectivity (Table 13–1). Despite the tendency to lump the contemporary SSRIs into the same class designation, significant structural and activity differences exist. Their chemical structures help illustrate this diversity (Figures 13–2 and 13–3). In contrast to paroxetine and sertraline, which exist as single isomers, fluoxetine, like citalopram, is a racemate. The family of SSRIs manifests diverse structural and activity relations. Such data are in vitro and thus subject to methodological variability (Thomas et al. 1987). Fluoxetine is less potent than paroxetine in vitro and less selective for 5-HT reuptake inhibition, relative to norepinephrine (NE), than citalopram. However, note that in vitro potency does not necessarily equate with in vivo dosing experience, clinical efficacy, or adverse-event profile.

Although the tricyclic antidepressants (TCAs), like the SSRIs, antagonize 5-HT receptors (Dempsey et al. 2005; Eisensamer et al. 2003), they also exhibit inhibitory activity at other receptor targets mediating their adverse-event profile (Hall and Ogren 1981; Snyder and Yamamura 1977; U'Prichard et al. 1978). These include histaminergic, α_1-adrenergic, and muscarinic receptors. For fluoxetine, the median inhibitory concentration (IC_{50}) at histaminergic and adrenergic sites is in the micromolar range and thus unlikely to be of clinical significance. Activity at the muscarinic receptor is negligible for fluoxetine. Stauderman et al. (1992) reported that fluoxetine and paroxetine inhibit the binding of ^{3}H-nitrendipine to L-type calcium channels; however, this was at concentrations that were probably in excess of those achieved during in vivo treatment of depression.

In summary, in vitro radioligand-binding techniques showed that fluoxetine had a lower probability of many of the troublesome side effects associated with TCAs and was relatively selective in its 5-HT reuptake inhibition. (For a general review of the synaptic effects of several SSRIs, compared with other antidepressants, see Richelson 1996.)

PHARMACOLOGICAL PROFILE

Serotonin

The action of any SSRI extends beyond the inhibition of 5-HT reuptake. At least 14 different 5-HT receptor subtypes reside at pre- and postsynaptic locations (Fuller 1996). Serotonin$_{1A}$ (5-HT$_{1A}$) binding sites include both somatodendritic and presynaptic autoreceptors (which inhibit 5-HT firing) and postsynaptic receptors. The latter are predominantly hippocampal, and their sensitivity is increased after chronic antidepressant exposure (Aghajanian et al. 1988; Elena Castro et al. 2003).

After chronic administration, many antidepressants downregulate or reduce the density of serotonin$_2$ (5-HT$_2$) binding sites in rat frontal cortex (Peroutka and Snyder 1980). Some, but not all, SSRIs have been associated with this effect (Fraser et al. 1988), and fluoxetine has been demonstrated to normalize 5-HT$_{1A}$ density in rats (Sodero et al. 2006). SSRIs, as a drug class, have been reported to normalize both 5-HT$_{1A}$ and 5-HT$_2$ receptor density among patients with depression (Leonard 1992).

The mechanisms by which fluoxetine and other SSRIs interact with the human serotonin transporter (SERT) are not yet fully understood. Some evidence suggests that fluoxetine's effect on SERT is partially based on SERT promoter polymorphism; it can lead to increased or decreased SERT expression, depending on an individual's genotype (Little et al. 2006). Further studies have shown that SERT may also be inhibited at the posttranslational stage, likely through multiple binding sites on the SERT molecule itself (Henry et al. 2006; Iceta et al. 2007).

Fluoxetine transiently inhibits dorsal raphe firing, decreases terminal autoreceptor function, and ultimately increases net 5-HT synaptic transmission within CA3 pyramidal cells in the hippocampus (Blier et al. 1988). Electrophysiological studies indicate that most antidepressants enhance net 5-HT transmission after chronic administration (Blier et al. 1990), albeit at different loci: the TCAs via enhanced sensitivity of postsynaptic 5-HT$_{1A}$ receptors, and the SSRIs (and MAO inhibitors [MAOIs]) via reduced sensitivity of somatodendritic (5 HT$_{1A}$) and terminal (serotonin$_{1D}$ [5-HT$_{1D}$]) autoreceptors. SSRIs and TCAs also exert an inhibitory effect on 5-HT$_3$ receptors in a noncompetitive fashion (Eisensamer et al. 2003). These observations of different mechanisms may help to explain why certain depressive symptoms that do not respond to one class of antidepressant will respond to another class and may also explain the enhanced response reported when combinations of antidepressant agents are used.

Norepinephrine

Chronic administration of most somatic treatments for depression downregulates or reduces the density of β-adrenergic binding sites in the brain (Bergstrom and Kellar 1979). These treatments include traditional NE-specific and mixed uptake inhibitors (Charney et al. 1981). However, results with the SSRIs have been less consistent (Johnson 1991). Despite its in vitro 5-HT selectivity, fluoxetine has been observed, with autoradiography, to induce β-adrenergic receptor downregulation. It has also been shown in at least one study to increase extracellular NE concentrations in rat prefrontal cortex after acute systemic administration; this effect was not observed with other SSRIs tested (Bymaster et al. 2002). Fluoxetine has also been demonstrated to potentiate the noradrenergic effects of bupropion (Li et al. 2002).

Most studies with SSRIs have not shown a consistent change in β-adrenergic binding or β-adrenergic-stimulated cyclic adenosine monophosphate (cAMP) production. However, Baron et al. (1988) reported that fluoxetine, when it was coadministered with desipramine, augmented the reduction in cortical β-adrenergic receptors expected with desipramine alone. In contrast, investigations with fluvoxamine, paroxetine, and citalopram have not yielded consistent results. In general, the greater the 5-HT selectivity of a compound, the less in vitro evidence for β-adrenergic downregulation has been seen. Thus, β-adrenergic downregulation may not be essential for clinical efficacy.

Current data do not support a significant effect on α-adrenergic receptor affinity or density by the SSRIs. Studies using radiolabeling to investigate fluoxetine (Wong et al. 1985) have shown relative inactivity at this site. Fluoxetine has been reported to reduce desipramine-induced release of growth hormone after 4 weeks of treatment (O'Flynn et al. 1991). This effect suggests a possible indirect activity at the α$_2$-adrenergic receptor.

In summary, although relative differences in adrenoreceptor affinity exist across the SSRI class, and fluoxetine may have more adrenergic activity than some of the other SSRIs, the clinical significance of these differences appears to be negligible.

Dopamine

Animal studies provide evidence that the serotonergic system may exert tonic inhibition on the central dopaminergic system. Serotonin has also been shown to decrease the generation of dopaminergic cells from mesencephalic precursors in rats, an effect mediated by 5-HT_4 and 5-HT_7 receptors found on glial cells (Parga et al. 2007). Thus, fluoxetine might diminish dopaminergic transmission consistent with anecdotes of extrapyramidal side effects (EPS) during fluoxetine therapy (Bouchard et al. 1989). 5-HT agonists, however, also exert a facilitatory influence on dopamine (DA) release (Benloucif and Galloway 1991), which can be antagonized by the 5-HT_1 blocker pindolol, and evidence suggests that SSRIs may actually sensitize mesolimbic DA receptors (Arnt et al. 1984a, 1984b). Furthermore, repeated administration of fluoxetine, citalopram, or paroxetine to rats increased spontaneous dopaminergic neuronal activity (Sekine et al. 2007), and chronic fluoxetine treatment also increased brain-derived neurotrophic factor (BDNF) expression within rat dopaminergic regions (Molteni et al. 2006).

Many structurally diverse antidepressants are associated with a net enhancement of mesolimbic DA (see Klimek and Maj 1990). The benefits of antidepressants in an animal model of depression can be antagonized by a dopamine$_1$ (D_1) (SCH-23390) or dopamine$_2$ (D_2) blocker (sulpiride) (Sampson et al. 1991). Repeated administration of several SSRIs was found to increase the hypermotility response to several dopaminergic agents, including amphetamine, methylphenidate (Arnt et al. 1984b), quinpirole (Maj et al. 1984), and apomorphine (Plaznik and Kostowski 1987).

The induction of catalepsy or the inhibition of apomorphine-induced catalepsy is not a property of the SSRIs. Both citalopram and fluoxetine have been inactive in displacing D_2 blockers (Peroutka and Snyder 1980). Baldessarini et al. (1992) reported that fluoxetine "even at high doses or with repeated treatment" demonstrated "no significant inhibition of the DA metabolism—increasing actions of haloperidol" (p. 191).

In summary, fluoxetine enhances central 5-HT transmission through increased output and/or increased postsynaptic receptor sensitivity (Blier et al. 1987). Fluoxetine's overall effects on the noradrenergic and dopaminergic systems are less straightforward and are also less likely to play a role in the drug's antidepressant effects. However, such changes alone, in any of the neurotransmitter systems, do not guarantee a clinically meaningful response (Charney et al. 1984). A change in baseline 5-HT function or a "permissive" set of interactions with other collocated neurotransmitter receptors is likely involved in the highly individualized responses in patients with depression.

PHARMACOKINETICS AND DISPOSITION

As demonstrated in Table 13–2, considerable pharmacokinetic variability exists within the SSRI class (Leonard 1992). Of particular note, discussion of drug half-life must also include consideration of the presence or absence of active metabolites. Fluoxetine is extensively metabolized by the liver's cytochrome P450 (CYP) system to its active metabolite, norfluoxetine. Fluoxetine is a potent CYP2D6 inhibitor, and norfluoxetine has a moderate inhibitory effect on CYP3A4 (Hemeryck and Belpaire 2002). The elimination half-life of norfluoxetine (4–16 days) is significantly longer than that of fluoxetine (4–6 days); in fact, norfluoxetine's half-life is the longest of any of the SSRIs or their active metabolites (see Table 13–2). Half-life is not significantly affected by hemodialysis or renal impairment (Aronoff et al. 1984).

The relatively long half-life of fluoxetine confers greater protection from the discontinuation syndrome that is associated with abrupt discontinuation or noncompliance related to interruption of treatment than more rapidly cleared SSRIs. Conversely, more prolonged vigilance for drug–drug interactions following discontinuation is required for fluoxetine; for example, a 5-week washout from fluoxetine is recommended before initiating an MAOI (Ciraulo and Shader 1990; Lane and Baldwin 1997). Variability in drug half-life is associated with a range in time to steady-state plasma concentrations, which does not clearly predict or correlate with onset of antidepressant activity.

MECHANISM OF ACTION

In the absence of pharmacological manipulation, the reuptake of 5-HT into the presynaptic nerve terminal typically leads to its inactivation. Fluoxetine, through blockade of the reuptake process, acutely enhances serotonergic neurotransmission by permitting 5-HT to act for an extended period of time at synaptic binding sites. A net result is an acute increase in synaptic 5-HT. One difference separating SSRIs from direct-acting agonists is that SSRIs are dependent on neuronal release of 5 HT for their action—that is, SSRIs can be considered augmenters of basal physiological signals, but they are not direct stimulators of postsynaptic receptor function and they are dependent on presynaptic neuronal integrity. These pharmacodynamic features might explain SSRI nonresponse. If the release of 5-HT from presynaptic neuronal storage sites is substantially compromised, and in turn, if net synaptic 5-HT concentration is negligible, a clinically meaningful response to an SSRI would not be expected.

Serotonin receptors also include a family of presynaptic autoreceptors that suppress the further release of 5-HT, thus limiting the degree of postsynaptic receptor stimulation that can be achieved. de Montigny et al. (1989) investigated the mechanism of action of several SSRIs and suggested that the enhanced efficacy of serotonergic synaptic transmission is not the result of increased postsynaptic sensitivity. Rather, longer-term SSRI treatment induced a desensitization of somatodendritic and terminal 5-HT autoreceptors. This desensitization would permit 5-HT neurons to reestablish a normal rate of firing, despite sustained reuptake blockade. These neurons could then release a greater amount of 5-HT (per impulse) into the synaptic cleft. This modification reportedly occurs over a time course that is compatible with the antidepressant response.

INDICATIONS AND EFFICACY

The U.S. Food and Drug Administration (FDA)–labeled indications for fluoxetine are major depressive disorder, obsessive-compulsive disorder (OCD), panic disorder, bulimia nervosa, and premenstrual dysphoric disorder (PMDD). We will review these as well as some other disorders for which fluoxetine is commonly used.

Major Depressive Disorder

Placebo-controlled, double-blind trials have established the superiority of fluoxetine over placebo (Kasper et al. 1992). Statistically significant reductions from baseline in the Hamilton Rating Scale for Depression (Ham-D; Hamilton 1960) score have been seen as early as the second week of treatment; however, the rate and quality of response to any SSRI are highly individualized (range, 10–42 days). Overall, the efficacy of fluoxetine has been found to be comparable to or slightly better than that of conventional TCAs (Cipriani et al. 2005; Wernicke et al. 1987) and comparable to that of venlafaxine (Nemeroff et al. 2007; Schatzberg and Roose 2006). Notwithstanding, in a survey of 439 clinicians, about one-quarter indicated that they believed SSRIs to be the most efficacious antidepressant class, despite a lack of clear empirical evidence (Petersen et al. 2002). Within the class of SSRIs, there is no clear and consistent evidence for superior effectiveness of one agent over another in primary care settings (Kroenke et al. 2001).

In general, the range for dose titration with most SSRIs is relatively narrow (see Table 13–2), and higher dosages are more often associated with increased adverse events (Altamura et al. 1988; M. Amin et al. 1989). Schweizer et al. (1990) reported that in a study of 108 subjects treated with 20 mg of fluoxetine for 3 weeks and then randomly assigned to either 20 mg or 60 mg for another 5 weeks, both groups did equally well after 8 weeks.

However, early implementation of high-dose therapy may be appropriate in some circumstances. Conversion of nonresponders by prescribing at the higher end of the dose range has been described with fluoxetine (Fava et al. 1992). Unfortunately, plasma-level studies have contributed little toward the understanding of the

dose–response relationship. Most studies have failed to confirm any relationship between clinical response and plasma concentration with fluoxetine (Kelly et al. 1989). This suggests that synaptic concentrations and/or pharmacodynamic effects are not accurately reflected by plasma levels.

Continued efficacy of fluoxetine during maintenance therapy has been established in several trials (Danion 1989; Dufour 1987; Ferrey et al. 1989; Montgomery et al. 1988; Reimherr et al. 1998). One trial reported a recurrence in 54 of 94 placebo subjects (57%) versus 23 of 88 fluoxetine-maintained subjects (26%) ($P < 0.0001$) who had at least 4.5 months of recovery before randomization (Montgomery et al. 1988). Study participants were required to have had at least two previous episodes.

Although fluoxetine is perceived as "activating," considerable evidence supports its utility in depression with anxious features. Montgomery (1989a) conducted a meta-analysis of several fluoxetine trials that indicated efficacy in depression featuring anxiety and psychomotor agitation. Similar findings have been reported by Jouvent et al. (1989) and Beasley et al. (1991).

In an attempt to improve compliance with long-term antidepressant treatment, a once-weekly formulation of fluoxetine was developed and approved. Although the concept appears reasonable and the preparation, a once-weekly enteric-coated 90-mg tablet, is safe and efficacious for continuation treatment (Schmidt et al. 2000), this formulation has not attracted widespread use, which suggests that a once-daily formulation may be convenient enough for most patients.

Obsessive-Compulsive Disorder

Clomipramine, a potent inhibitor of both 5-HT and NE reuptake, was observed more than 30 years ago to reduce obsessive-compulsive symptoms (Renynghe de Voxurie 1968). The superior benefit of this potent serotonergic TCA over desipramine represents a cornerstone in the 5-HT hypothesis of OCD (Benkelfat et al. 1989). Fluoxetine has been shown to be effective in OCD independent of a patient's comorbid mood status (Jenike et al. 1989). Patients who have OCD may require higher doses of medication and longer treatment periods than do patients with depression to determine response. Currently, clomipramine and the SSRIs are considered to be the first-line agents for treatment of OCD (Kaplan and Hollander 2003).

A precise explanation of this selective 5-HT advantage in OCD is unknown. A heightened level of metabolic activity in the orbital region and caudate dysfunction have been reported by Baxter et al. (1992) and may be normalized by either somatic (fluoxetine 60–80 mg) or behavioral interventions. Hypersensitivity of the serotonergic system has been theorized. Receptor downregulation associated with long-term SSRI therapy has been offered as a potential explanation of clinical response (Zohar et al. 1988). This hypothetical neuroadaptation is supported by a positive correlation between symptomatic improvement from baseline and cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) (Thorén et al. 1980) or platelet 5-HT concentration (Flament et al. 1985). Chronic administration of fluoxetine attenuates ipsapirone-induced hypothermia and adrenocorticotropic hormone (ACTH) and cortisol release among patients with primary OCD. Although these data support a model of drug-induced 5-HT_{1A} subsensitivity and/or dampened postreceptor signal, the magnitude of change fails to correlate with the degree of clinical improvement (Lesch et al. 1991). An SSRI-mediated decrease in 5-HT responsivity is consistent with the observed latency in symptomatic improvement.

Because OCD is a chronic disorder, prolonged fluoxetine therapy may be necessary. In patients whose symptoms have been minimally or only moderately reduced with SSRI treatment, numerous augmentation strategies have been proposed, including tryptophan, fenfluramine, lithium, buspirone, trazodone, or a neuroleptic (see Goodman et al. 1992). In addition, fluoxetine has shown efficacy in children and adolescents with OCD (Geller et al. 2001). In so-called OCD spectrum disorders, such as skin picking (Bloch et al. 2001) and body dysmorphic disorder (Phillips et al. 2002), controlled trials also indicate efficacy for fluoxetine.

Panic Disorder

SSRIs are the drugs of choice in the prevention of panic attacks and in the treatment of panic disorder. Positive results from double-blind, placebo-controlled trials in patients with panic disorder are available for fluoxetine (Michelson et al. 2001). In general, patients with panic disorder need a low initial dose of fluoxetine (e.g., 10 mg); however, often usual antidepressant dosing for optimal response (e.g., 20–80 mg) is required. The initial low dose serves to minimize early side effects in anxious patients who are particularly sensitive to somatic symptoms of anxiety, and it sets the stage for long-term compliance. The recurrent and chronic nature of panic disorder requires individual medication regimens that may include multiple agents as well as variable dosages.

Eating Disorders

Manipulation of central 5-HT results in significantly altered feeding behaviors (e.g., an increased satiety response) (Carruba et al. 1986). Blundell (1986) reported that pharmacological enhancement of 5-HT reduced meal size, rate of eating, and body weight. The predominant locus of this 5-HT effect is likely within the hypothalamus and may be mediated through gene expression of neuropeptide Y (NPY) and pro-opiomelanocortin (POMC) (Myung et al. 2005). In general, the ability of an antidepressant to diminish appetite and, in turn, to reduce weight is related to its ability to block 5-HT uptake (Angel et al. 1988). One exception may be paroxetine, a highly potent 5-HT uptake inhibitor that, compared with conventional TCAs, was associated with a similar proportion of subjects in clinical trial experience reporting weight gain (Dechant and Clissold 1991). Paroxetine, compared with fluoxetine and sertraline over time in patients with depression, was associated with more significant weight gain (Fava et al. 2000). Selective 5-HT_{1A} activation in some patients may influence weight gain (Dourish et al. 1986).

Bulimia Nervosa

5-HT involvement in bulimia nervosa has been based on several observations (Jimerson et al. 1989; Kaye et al. 1988). Kaye et al. (1988) hypothesized that variations in the ratio of tryptophan to other amino acids, consequent to recurrent bingeing and vomiting, mediated both satiety and mood. Some patients with bulimia nervosa, independent of mood status, manifest a blunted prolactin response to *m*-chlorophenylpiperazine (m-CPP). This has been interpreted as evidence of postsynaptic 5-HT hypersensitivity within select hypothalamic pathways (Brewerton et al. 1990).

Goldbloom et al. (1988) reported that the V_{max} (maximum velocity)—the maximum amount of substrate per unit of time that an enzyme can break down or synthesize at saturation (i.e., when all of the enzyme's active sites are filled)—of platelet 5-HT uptake was increased among bulimic patients without depression. Jimerson et al. (1989) observed a significant inverse association between CSF 5 HIAA and symptom severity. However, much of the support for a 5-HT role in bulimia nervosa comes from pharmacotherapeutic experience. Agents with at least some degree of 5-HT uptake inhibition have been useful in bulimia nervosa (see Brewerton et al. 1990).

Clinical trials with fluoxetine have found a positive treatment effect on binge eating and purging behaviors (Goldstein et al. 1995). In a large placebo-controlled trial, Enas et al. (1989) studied dosing of 20 mg versus 60 mg of fluoxetine in 382 female outpatients with bulimia. A clinical benefit was observed in binge frequency, purging, mood, and carbohydrate craving. In a smaller study of 91 female patients in a primary care setting, women assigned to fluoxetine kept more physician appointments, exhibited greater reductions in binge eating and vomiting, and had a greater improvement in psychological symptoms than those assigned to placebo (Walsh et al. 2004). Continued treatment with fluoxetine is associated with improvement and decreased risk of relapse (Romano et al. 2002).

Anorexia Nervosa

A 5-HT disturbance in anorexia nervosa was postulated by Fanelli et al. (1986). Coppen et al. (1976) reported a reduction in plasma L-tryptophan among patients with anorexia. Others have observed that platelet imipramine binding is decreased (Weizman et al. 1986); however, these findings have not been uniformly replicated. Brewerton et al. (1990) suggested that hypothalamic 5-HT responsivity at or beyond postsynaptic sites is abnormal in subjects with anorexia nervosa.

Pharmacological trials with SSRIs in patients with anorexia nervosa have been relatively sparse. Kaye et al. (1991) suggested that fluoxetine may help maintain body weight in patients with anorexia nervosa who have gained weight. This group also completed a similar study with fluoxetine under controlled conditions, suggesting some benefit for fluoxetine in improving outcome and preventing relapse (Kaye et al. 2001). On the other hand, Walsh et al. (2006) found no benefit for continued treatment with fluoxetine after weight restoration in a randomized, double-blind, placebo-controlled trial of 93 patients. Efficacy of SSRIs has been linked to the food obsessions of many patients with eating disorders.

Premenstrual Dysphoric Disorder

Several randomized, blinded, placebo-controlled trials that used various diagnostic criteria and outcome measures have established the efficacy and tolerability of fluoxetine in the treatment of PMDD (Menkes et al. 1993; Pearlstein et al. 1997; Steiner et al. 1995; Su et al. 1993, 1997; Wood et al. 1992). In the largest study,

313 women with DSM-III-R-defined late luteal phase dysphoric disorder (American Psychiatric Association 1987) received 20 mg of fluoxetine, 60 mg of fluoxetine, or placebo daily for six menstrual cycles after a two-cycle placebo washout period (Steiner et al. 1995). One hundred eighty women completed the study. Both doses of fluoxetine were superior to placebo, beginning at the first menstrual cycle and continuing throughout the six cycles. More patients treated with 60 mg of fluoxetine discontinued because of adverse events than did patients treated with 20 mg of fluoxetine or placebo. More patients treated with placebo discontinued because of lack of response than did patients treated with either fluoxetine dose. In a subsequent study of 34 women, fluoxetine was significantly superior to bupropion and placebo in treating PMDD (Pearlstein et al. 1997).

Anger and Aggression

Diminished serotonergic activity has been implicated in the personality features of impulsivity, anger, hostility, and aggression (Coccaro et al. 1989). These clinical attributes best associate with DSM-IV (American Psychiatric Association 1994) Cluster B personality disorders. Fluoxetine reduced impulsivity in small groups of patients with borderline personality disorder (Cornelius et al. 1991; Norden 1989). Fluoxetine significantly reduced anger attacks in patients with and without depression (Fava et al. 1991, 1993, 1996; Rubey et al. 1996; Salzman et al. 1995).

Posttraumatic Stress Disorder

Fluoxetine significantly reduced symptoms of posttraumatic stress disorder (PTSD), compared with placebo, in 64 patients (veterans and nonveterans), as measured by the Clinician-Administered PTSD Scale (CAPS) (Van der Kolk et al. 1994). It also showed efficacy by week 6 in a large double-blind, placebo-controlled trial (Martenyi et al. 2002).

Premature Ejaculation

SSRIs, including fluoxetine, are effective in the treatment of premature ejaculation, although increased latency to ejaculation is highest with paroxetine (Waldinger et al. 1998). In a 1-year follow-up study, patients treated with fluoxetine (20 mg/day or less) in combination with sexual behavior therapy reported significant improvement in ejaculation latency (Graziottin et al. 1996). Another study demonstrated efficacy from a weekly fluoxetine dose of 90 mg (Manasia et al. 2003). Clear-cut dosing recommendations have not been clarified, however, and titration (upward or downward) may be necessary.

Pain Syndromes

Fluoxetine has shown efficacy in reducing pain associated with diabetic neuropathy (Max et al. 1992). Fluoxetine (20 mg/day) improved scores on measures of pain and discomfort in subjects with fibromyalgia, compared with subjects on placebo (Arnold et al. 2002; Goldenberg et al. 1996). The effect of fluoxetine combined with amitriptyline was superior to the effect of either agent used alone. Fluoxetine reduced the number of attacks in patients with migraine headaches (Saper et al. 1994). More recent work has demonstrated that antidepressants that also affect the NE system (i.e., serotonin–norepinephrine reuptake inhibitors [SNRIs]) are more effective than the SSRIs in treating neuropathic pain (Mochizucki 2004; L. H. Pedersen et al. 2005). In fact, the SNRI duloxetine has received FDA approval for the treatment of neuropathic pain.

Alcohol Abuse and Dependence

A substantial amount of evidence supports a 5-HT dysfunction in alcohol abuse and dependence. Animal studies have shown that increased 5-HT levels reduce alcohol consumption (Farren 1995). For example, Murphy et al. (1988) reported beneficial effects with fluoxetine and fluvoxamine in reducing alcohol intake in a rat model.

Although results are not consistent, some clinical trials with SSRIs have reported reduced alcohol consumption in patients with and without depression, in contrast to patients treated with TCAs, which have less robust efficacy (Cornelius et al. 1997; Lejoyeux 1996). A precise mechanism for the role of SSRIs in the treatment of alcohol dependence is not understood. To date, the beneficial effect, if any, appears to be independent of antidepressant activity (Naranjo et al. 1986, 1990). More work is needed to determine the specific patient subpopulations that might benefit most from SSRIs (see Gorelick 1989).

From a risk–benefit assessment, it is reassuring that fluoxetine does not appear to potentiate the effects of ethanol (Lemberger et al. 1985) and does not carry a high risk of fatal poisoning when taken in combination with alcohol (Koski et al. 2005). SSRIs may help selected patients with alcohol dependence in recovery when these

drugs are used as part of a multifaceted treatment program.

Obesity

SSRIs have been extensively investigated for an effect on food consumption. This interest stems from evidence that perturbation of 5-HT receptors modifies animal feeding behavior (Garattini et al. 1986). This modification appears to be independent of a local gastrointestinal effect (e.g., the perception of nausea). 5-HT innervation to the hypothalamus influences satiety and may selectively affect carbohydrate consumption (Wurtman et al. 1981). In one large trial, 458 patients were treated for 52 weeks with fluoxetine (60 mg/day) or placebo (Goldstein et al. 1994). Weight loss was significantly greater in the fluoxetine-treated group at 28 weeks, but not at 52 weeks. Long-term benefits may be better sustained when fluoxetine is combined with behavior modification (Marcus et al. 1990).

The broad involvement of the serotonergic system in modulating behavior and cognition supports the wide potential utility of SSRIs.

Other Medical Conditions

Fluoxetine has been evaluated and observed to be efficacious in a variety of medical conditions, including poststroke depression, fibromyalgia, chronic pain, and depression in cancer patients. It has also proved useful in some patients with chronic fatigue syndrome.

SIDE EFFECTS AND TOXICOLOGY

Safety and a favorable side-effect profile, as well as the lack of multiple receptor affinity that mediates adverse events associated with TCAs, distinguish fluoxetine and other SSRIs from TCAs. Medications in the SSRI class generally have similar side-effect profiles.

For most patients, SSRIs are better tolerated than TCAs, based on the number of early trial discontinuations attributable to an adverse event (see Boyer and Feighner 1991). In general, for three-arm trials, the incidence of early discontinuation due to an adverse event was 5%–10% for placebo, 10%–20% for SSRIs, and 30%–35% for TCAs. The SSRIs, presumably by enhancement of 5-HT within the CNS, may induce agitation, anxiety, sleep disturbance, tremor, sexual dysfunction (primarily anorgasmia), or headache. Baseline clinical features do not appear to predispose patients to these adverse events (Montgomery 1989b). Although CNS adverse events may occur with SSRIs, Kerr et al. (1991) suggested that these drugs have a more favorable profile of behavioral toxicity overall than do conventional TCAs.

Because the enteric nervous system is richly innervated by 5-HT, adverse events may include altered gastrointestinal motility and nausea. Certain autonomic adverse events, including dry mouth, sweating, and weight change, also occur.

Fluoxetine decreases rapid eye movement (REM) and increases non–rapid eye movement (NREM) sleep at dose ranges of 5–40 mg/kg in rodent models (Gao et al. 1992). This is a common property of many antidepressant medications. Of interest, fluoxetine induces higher rates of sedation as dosages are increased.

As was discussed earlier in this chapter, fluoxetine is unlikely to alter DA function; nonetheless, some side effects, such as hyperprolactinemia, extrapyramidal symptoms, sexual and cognitive dysfunction, galactorrhea, mammary hypertrophy, and gynecomastia, have been attributed to SSRI effects on the dopaminergic system (Damsa et al. 2004). Anecdotal reports of EPS (Meltzer et al. 1979) associated with SSRIs are not more frequent than those reported historically with TCAs (Fann et al. 1976; Zubenko et al. 1987), MAOIs (Teusink et al. 1984), or trazodone (Papini et al. 1982). Very rare events, including arthralgia, lymphadenopathy, syndrome of inappropriate antidiuretic hormone (SIADH) secretion, agranulocytosis, and hypoglycemia, have been reported during clinical trials or postmarketing surveillance; however, causality typically is uncertain.

One additional rare and life-threatening event associated with all SSRIs (and, more prominently, their interaction with MAOIs or other 5-HT enhancers) is the central 5-HT syndrome. This phenomenon appears to represent an overactivation of central 5-HT receptors and may manifest with features such as abdominal pain, diarrhea, sweating, fever, tachycardia, elevated blood pressure, altered mental state (e.g., delirium), myoclonus, increased motor activity, irritability, hostility, and mood change. Severe manifestations of this syndrome can induce hyperpyrexia, cardiovascular shock, or death. There are insufficient data to rate one MAOI or SSRI as more or less likely to be associated with 5-HT syndrome. The risk of 5-HT syndrome seems to be increased when an SSRI is administered temporally with a second 5-HT–enhancing agent (e.g., an MAOI) (Marley and Wozniak 1984a,

1984b). When switching from an SSRI to an MAOI, drug half-life (and that of any active metabolite, where applicable) should serve as a guide to the length of the washout period. A standard recommendation is to wait at least five times the half-life of the SSRI or its metabolite, whichever is longer, before administering the next serotonergic agent (for a review, see Lane and Baldwin 1997). For fluoxetine, this means a minimum 5-week washout period.

Although some variability in adverse-event frequency has been reported among the SSRIs, all of the SSRIs are characterized by the above-mentioned features. Tolerance to an adverse event may change with dose and/or length of exposure; higher doses are typically associated with higher rates of adverse events (Bressa et al. 1989). Many events, such as activation, are transient, usually beginning early in the course of therapy and then remitting (Beasley et al. 1991). Comparisons between A.M. and P.M. administration did not identify differences in efficacy (Usher et al. 1991). Individual patient differences suggest the need for some flexibility in dosing schedules. TCAs behave like type IA antiarrhythmics; therefore, in a dose-dependent fashion, they may retard His-Purkinje conduction. SSRIs are essentially devoid of this property. In clinical trials, the incidence of increased heart rate or conduction disturbance has been very low with fluoxetine (Fisch 1985). For a review of the relative side-effect profiles of TCAs and SSRIs, see Brambilla et al. (2005).

SPECIFIC ISSUES

Suicidality

Evidence implicating 5-HT in suicide or violence is compelling. Reduced CSF 5-HIAA concentrations correlate highly with completed suicides in patients with depression (Edman et al. 1986; Ninan et al. 1984). In vitro binding assays have shown an increased density (B_{max}) of 5-HT_2 receptors in individuals with depression and suicidal tendencies (Pandey et al. 1990). Both observations are consistent with a relative state of 5-HT depletion among subjects with suicidal tendencies. The American College of Neuropsychopharmacology (1992) reviewed evidence showing that antidepressants result in substantial improvement or remission of suicidal ideation and impulses in the vast majority of patients. SSRIs were thought to potentially "carry a lower risk for suicide than older tricyclic antidepressants" (p. 181) when taken in overdose. Furthermore, the task force stated that no evidence indicated that SSRIs triggered emergent suicidal ideation above base rates associated with depression. In addition, Warshaw and Keller (1996) determined that fluoxetine use did not increase the rate of suicide in a group of 654 patients with anxiety disorders. In a large retrospective review of patients receiving one or more of 10 antidepressants (including fluoxetine), Jick et al. (1995) concluded that the risk for suicide was similar among all agents.

Concern about suicidality surged in 2003 after the industry alerted the FDA that there might be an increased risk of suicide-related adverse events in children being treated with paroxetine. The FDA's review of available data found that approximately 4% of children taking SSRI medications reported or exhibited suicidal thinking or behavior (including suicide attempts), twice the rate of those taking placebo. No completed suicides occurred among nearly 2,200 children treated with SSRIs, however.

The FDA's review was followed by a number of other studies examining this issue, including a meta-analysis of 24 pediatric trials of nine antidepressant drugs by Hammad et al. (2006). These authors found a modestly increased risk of suicidality (risk ratio = 1.66) for SSRIs in depression trials (95% confidence interval = 1.02–2.68). This risk must be balanced against the benefit—in the form of general improvement in mood and overall functioning—experienced by most depressed patients when they are placed on antidepressant therapy. In most cases, the therapeutic benefit of SSRIs will outweigh the risk of increased suicidal thoughts or behaviors (Bridge et al. 2007).

Black Box Warning

On March 22, 2004, the FDA issued a public health advisory warning of the risk of worsened depression and suicidality in children and adolescents being treated with antidepressant medications. This was followed by placement of a black box warning on the packaging of all antidepressant medications, revised in 2006 to include adults through age 25 years (for the full text of the 2007 revision, see http://www.fda.gov/cder/drug/antidepressants/antidepressants_label_change_2007.pdf).

Pregnancy and Lactation

Given the widespread use of SSRIs and the high prevalence of mood disorders during the childbearing years, it is likely that these agents are being used during pregnancy and breast feeding. Published information about the use

and safety of SSRIs in this special population is greatest for fluoxetine. Goldstein et al. (1997) evaluated the outcomes of 796 prospectively identified pregnancies with confirmed first-trimester exposure to fluoxetine. Historical reports of newborn surveys were used for comparison. Abnormalities were observed in 5% of the fluoxetine-exposed newborns, which was consistent with historical controls.

Pregnancy outcomes and follow-up cognitive and behavioral assessments of 135 children exposed in utero to a TCA or fluoxetine (55 infants) were compared with those in a control group of infant–mother pairs (Nulman et al. 1997). The incidence of major malformations and perinatal complications was similar among the three groups. No statistically significant differences in mean global intelligence quotient (IQ) scores or language development were found in the children of mothers who received a TCA or fluoxetine or control mothers. There were also no differences among the groups on several behavioral assessments. The results of children exposed during the first trimester were not different from those of children exposed throughout the pregnancy. Prospectively derived data are not available for paroxetine, sertraline, fluvoxamine, or citalopram.

Fluoxetine is secreted into breast milk (Hendrick et al. 2001). The implications of this minimal exposure are unclear, but one naturalistic study (Taddio et al. 1996) and two case reports (Burch and Wells 1992; Isenberg 1990), with a total of 13 infants, noted no adverse effects in these infants during the short-term study periods. One case report did describe adverse events in a breast-fed infant whose mother was taking fluoxetine (Lester et al. 1993).

Fractures

Several studies have found a 1.5- to twofold increase in the risk of bone fractures in elderly patients taking TCAs or SSRIs. In a cohort study of more than 8,000 community-dwelling older women followed for almost 5 years, the risk of nonspinal fractures increased by a factor of 1.7 for those taking TCAs or SSRIs (Ensrud et al. 2003). More recently, a randomized cohort of 5,008 community-dwelling adults older than 50 years followed for a 5-year period found a 2.1-fold increase in the rate of fractures for those taking SSRIs (Richards et al. 2007). In this study, SSRI use was also associated with increased risk of falls, lower bone mineral density at the hip, and a trend toward lower bone mineral density at the spine in a dose- dependent fashion.

Animal models have so far failed to consistently demonstrate significant changes in bone architecture as a result of SSRI exposure, and the exact mechanism by which SSRIs may lead to fractures in humans is still unclear. There does appear to be, however, a functional serotonin 5-HT system in osteoclasts and osteoblasts involving both receptor activation and 5-HT reuptake (Battaglino et al. 2007).

SSRI Discontinuation Syndrome

Discontinuation symptoms have been described with several classes of antidepressants, including TCAs and MAOIs. SSRI discontinuation symptoms have been reported most frequently with paroxetine (short elimination half-life and no active metabolite) and least frequently with fluoxetine (long elimination half-lives of parent compound and active metabolite) (Haddad 1997; Stahl et al. 1997). SSRIs are not drugs of abuse; when these agents are discontinued, patients show neither the characteristic abstinence syndrome of CNS-depressant withdrawal nor drug-seeking behavior. The most common physical symptoms are dizziness, nausea and vomiting, fatigue, lethargy, flulike symptoms (e.g., aches and chills), and sensory and sleep disturbances. The psychological symptoms most commonly reported are anxiety, irritability, and crying spells. For most patients, the discontinuation symptoms are different from the adverse effects that they may have experienced while taking an SSRI. Discontinuation symptoms most often emerge within 1–3 days (Schatzberg et al. 1997).

Until recently, most information about SSRI discontinuation syndrome came from case reports or retrospective analyses. Rosenbaum et al. (1998) compared the effects of a 5- to 8-day abrupt discontinuation period from fluoxetine, paroxetine, or sertraline in three groups of patients with depression receiving maintenance therapy. Patients from the paroxetine and sertraline groups had a significant increase in adverse events, whereas patients in the fluoxetine group experienced no increase in adverse events.

In a more extended evaluation, the effects of abrupt discontinuation of fluoxetine were studied in 195 patients with depression (Zajecka et al. 1998). Patients whose depression remitted while taking fluoxetine were randomly assigned to continue fluoxetine (20 mg/day) or to discontinue abruptly to placebo, and they were monitored for 6 weeks. Reports of adverse events were similar for both groups.

In summary, SSRIs with short half-lives (paroxetine and fluvoxamine) and related drugs, such as venlafaxine, should be tapered. Fluoxetine does not require tapering because of its extended half-life.

Overdose

A major advantage of SSRIs, relative to other antidepressants, has been their superior therapeutic index (Cooper 1988; O. L. Pedersen et al. 1982). The number of deaths per 1 million prescriptions, across several SSRIs (0–6), is substantially lower than that for conventional TCAs (8–53) or MAOIs (0–61) (Leonard 1992).

Borys et al. (1992) reported on 234 cases of fluoxetine overdose (serum level = 232–1,390 ng/mL) obtained in a prospective multicenter study. Fluoxetine was the sole ingestant in 87 cases; in the remaining 147 cases, it was taken in combination with alcohol and/or other drugs. Common symptoms included tachycardia, sedation, tremor, nausea, and emesis. The authors concluded that the emergent symptoms were minor and of short duration; thus, aggressive supportive care "is the only intervention necessary" (p. 115).

DRUG–DRUG INTERACTIONS

Although the potential for significant interactions exists, SSRIs are unlikely to be associated with many of the conventional problems seen with the earlier antidepressants. These problems include the cumulative CNS-depressant effects with alcohol, anticholinergic agents, or antihistaminic compounds. The structural differences among SSRIs (see Figure 13–2) offer a basis for some intraclass differences. Lithium concentrations are generally unaffected.

One potential for clinically relevant antidepressant pharmacokinetic interactions is based on the drug effect on the cytochrome P450 family of enzymes (Brosen and Gram 1989). For example, SSRIs are both substrates for and inhibitors of oxidation via cytochrome P450 2D6. Crewe et al. (1992) ranked the potency of 2D6 inhibition for serotonergic antidepressants, revealing the most clinically relevant effects on 2D6 for paroxetine and fluoxetine and less relevant effects for sertraline, fluvoxamine, citalopram, clomipramine, and amitriptyline.

Through inhibition of 2D6, fluoxetine may elevate the concentration of concomitantly administered drugs that rely on this enzyme for metabolism. This has particular clinical relevance when the second agent has a narrow therapeutic index. Examples of such agents include flecainide, quinidine, carbamazepine, propafenone, TCAs, and several antipsychotics (Rudorfer and Potter 1989). The clinical consequence of such an interaction may either enhance or impair efficacy and/or heighten the adverse-event profile.

The data with respect to fluoxetine's inhibition of other cytochrome P450 enzymes, such as 3A3/4, 2C9, and 2C19, are less consistent, but the potential for interaction exists.

CONCLUSION

Fluoxetine has been shown to be a safe and effective drug that has proved to be better tolerated than TCAs and to have a superior safety profile in overdose for patients with comorbid medical illness. Evidence suggests a broad utilitarian role for fluoxetine across a spectrum of psychopathology.

Chapter 14. Sertraline

HISTORY AND DISCOVERY

Research has implicated dysregulation of serotonin (5-HT) in mood and anxiety disorders. Despite the effectiveness of the monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs), which exert their effects by inhibiting the enzymatic degradation and reuptake of monoamines, respectively, side effects and potential serious adverse events limited their utility. Researchers thus identified compounds that are selective in blocking neurotransmitter reuptake and yet have little agonist and antagonist activity at receptors thought to be associated with adverse effects. Sertraline [(+)-*cis*-(1S,4S)-4-(3,4-dichlorophenyl)-1,2,3,4-tetrahydro-*N*-methyl-1-naphthylamine], a naphthylamino compound that is structurally different from MAOIs and TCAs (Figure 14–1), is one of this class of drugs (Guthrie 1991; Heym and Koe 1988).

FIGURE 14–1. Chemical structure of sertraline.

For the 12 months ending June 2006, it has been estimated that sales of sertraline (under the brand name Zoloft) in the United States exceeded $3 billion (Rancourt 2006). In August 2006, a generic formulation of sertraline became available in the United States, and within the first 2 weeks of its availability, the substitution rate exceeded 77% (Block 2006).

STRUCTURE–ACTIVITY RELATIONS

Sertraline hydrochloride specifically blocks the reuptake of 5-HT in the soma and terminal regions of serotonergic neurons. The ability of sertraline to inhibit 5-HT reuptake is approximately 20-fold higher than its capacity to inhibit uptake of either norepinephrine or dopamine (DA) (Heym and Koe 1988). However, sertraline is more potent at blocking DA receptor uptake than are other selective serotonin reuptake inhibitors (SSRIs) and TCAs (Hiemke and Härtter 2000; Richelson 1994).

Serotonin neurons in the midbrain raphe nuclei have inhibitory autoreceptors in both the soma (serotonin$_{1A}$ [5-HT$_{1A}$] receptors) and terminal area (serotonin$_{1B}$ [5-HT$_{1B}$] receptors) that are stimulated by the acute increase in 5-HT. Thus, the immediate effect of serotonin transporter (5-HTT) blockade is to increase the amount of 5-HT in axosomatic synapses and to decrease neuronal firing

(Blier 2001; Blier et al. 1990; Heym and Koe 1988). Over several weeks, these autoreceptors are desensitized and firing rates increase.

Unlike the older TCAs, sertraline has little appreciable antagonistic effect on histamine$_1$ (H_1), muscarinic, or dopamine$_2$ (D_2) receptors and thus is associated with few difficulties with severe constipation, drowsiness, and dry mouth (Hiemke and Härtter 2000; Richelson 1994). The antagonism of α_1-adrenoreceptors by sertraline is at least 10-fold more than that of other SSRIs (Hiemke and Härtter 2000), although this antagonism does not translate into clinically meaningful hypotension or reflex tachycardia. However, there is a report suggesting that sertraline decreases sympathetic nervous system activity, a property consistent with α receptor blockade (Shores et al. 2001). It is also possible that the decrease in sympathetic response is related to stimulation of the 5-HT_{1A} receptors noted above. Given that sertraline and other medications in its class exhibit anxiolytic effects, it is possible that the decrease in sympathetic activity is related to these effects.

Sertraline is metabolized to desmethylsertraline (see section "Pharmacokinetics and Distribution" below). This compound is approximately one-tenth as active in blocking the reuptake of 5-HT; it also lacks antidepressant activity in animal models (Heym and Koe 1988).

PHARMACOLOGICAL PROFILE

Among the various antidepressant agents that block the 5-HTT, sertraline is second only to paroxetine in potency for 5-HT reuptake blockade, as demonstrated in animal models (Hiemke and Härtter 2000; Owens et al. 2001; Richelson 1994). The selectivity of sertraline over norepinephrine follows that of escitalopram (Hiemke and Härtter 2000; Owens et al. 2001), although other work suggests greater selectivity for fluvoxamine than for sertraline (Richelson 1994). The relative selectivity for the 5-HTT, compared with the dopamine transporter (DAT), is lowest for sertraline (Owens et al. 2001).

Sertraline exhibits inhibitory activity on several cytochrome P450 (CYP) enzymes. The ability of the compound to slightly elevate dextromethorphan and desipramine supports modest inhibition of CYP2D6 (Hiemke and Härtter 2000; Ozdemir et al. 1998; Preskorn 1996). It has little appreciable inhibition of CYP1A2, even when used at higher doses (Ozdemir et al. 1998). A very mild elevation of CYP2C9/10 substrates has been found in several studies (Preskorn 1996). Sertraline has complex effects on the CYP3A3/4 enzyme system: it initially shows slight inhibition, but it also induces this system, albeit modestly, over time (Preskorn 1996).

PHARMACOKINETICS AND DISTRIBUTION

Sertraline is absorbed slowly via the gastrointestinal tract, with peak plasma levels occurring between 6 and 8 hours after ingestion (Warrington 1991). The delay in achieving peak levels may be the result of enterohepatic circulation (Hiemke and Härtter 2000; van Harten 1993). When sertraline is taken with food, the peak level decreases to about 5.5 hours ("Zoloft" 2001). The medication is more than 95% protein bound; however, because it binds weakly to α_1-glycoproteins, it does not cause substantial displacement of other protein-bound drugs (Preskorn 1996).

The volume of distribution (V_d) of sertraline is large in that it exceeds 20 L/kg. The distribution is larger in young females than in young males (Warrington 1991). In animal models, the concentration of sertraline is 40 times higher in brain than in plasma (Hiemke and Härtter 2000).

The elimination half-life of sertraline is 26–32 hours, and steady-state levels are achieved after 7 days. Sertraline shows linear pharmacokinetics within a range of 50–200 mg/day (Warrington 1991) and does not appear to inhibit or induce its own metabolism. Peak plasma levels are somewhat lower in young males, compared with females and older males (Ronfeld et al. 1997; Warrington 1991; "Zoloft" 2001), and the elimination rate constant is higher in young males than in females or older males (0.031/hour in young males; 0.022/hour in young females and 0.019/hour in older males and females).

In children between the ages of 6 and 17 years, weight-corrected metabolism is more rapid. The maximum concentration and area under the curve (AUC) are 22% lower than in adults. Despite the greater efficiency, the smaller body mass found in children suggests that lower dosages should be used ("Zoloft" 2001).

Sertraline is metabolized in the liver via oxidative metabolism; the concentration of the primary metabolite, desmethylsertraline, is up to threefold higher than that of the parent compound (Hiemke et al. 1991; Ronfeld et al. 1997; Warrington 1991). Desmethylsertraline levels are also lower in young males than in females and elderly males. The peak concentration (t_{max}) of desmethylsertraline is attained more quickly in young females than in young males (6 hours in young females vs. 9 hours in young males, 8 hours in older females, and 14 hours in older males) (Warrington 1991). The half-life of desmethylsertraline is 1.6–2.0 times that of the parent compound (Warrington 1991).

As mentioned above, desmethylsertraline is the major metabolite of sertraline; minor metabolites include a ketone and an alcohol compound (Warrington 1991). Less than 0.2% of an oral dose of sertraline is excreted unchanged in urine, whereas approximately 50% is found in feces. The enzymes involved in metabolism of sertraline to desmethylsertraline remain unclear (Greenblatt et al. 1999). Although six different CYP enzymes have the capacity to catalyze this reaction, none accounts for more than 25% of sertraline's clearance. The contribution of each CYP enzyme is dependent on not only the protein's activity on the substrate, as evidenced through in vitro models, but also the abundance of the enzyme. Given these properties, one computer model found that the greatest contribution to the demethylation of sertraline is from 2C9 (~23%), with 3A4 and 2C19 each contributing about 15%, 2D6 adding 5%, and 2B6 contributing 2% to the process (Greenblatt et al. 1999; Lee et al. 1999). The percentages could vary in a particular individual, depending on the amount of enzyme available or enzyme inhibition that occurs. However, given that multiple CYP enzymes are involved in this metabolic process, concurrent medications with specific CYP inhibition are not likely to impair metabolism of sertraline (Greenblatt et al. 1999).

Patients with liver disease experience decreased sertraline metabolism (Hiemke and Härtter 2000). For individuals with mild liver impairment, the half-life of drug may be increased threefold ("Zoloft" 2001). It is likely to be greater in patients with severe impairment, such as in those with cirrhosis. On the other hand, renal impairment does not appreciably influence the metabolism of sertraline (Hiemke and Härtter 2000).

MECHANISM OF ACTION

The means by which antidepressants exert their therapeutic action is still unknown, although some of the properties noted above have been related to hypothetical mechanisms (Blier 2001; Blier et al. 1990). As previously noted, the immediate effect of sertraline is to decrease neuronal firing rates. This is followed by normalization and an increase in firing rates, as autoreceptors are desensitized. Normalization in firing coincides with the time course of patient improvement in depressive symptoms and has been theoretically linked to the mechanism of action. It has been suggested that the downregulation of autoreceptors is important in correcting the depressive disorder (Blier 2001; Blier et al. 1990). However, the activity of noradrenergic neurons is also affected. As activity in the presynaptic neuron increases, noradrenergic neurons are stimulated by postsynaptic 5-HT receptors located on noradrenergic nerve terminals. This leads to eventual downregulation of β-adrenergic receptors, a property caused by many, but not all, antidepressant agents (Frazer and Scott 1994; Guthrie 1991).

Not inconsistent with the above are more recent results suggesting that SSRI treatment decreases production of 5-HT_{1B} messenger RNA (mRNA), the message for a regulatory autoreceptor on dorsal raphe neurons that controls the amount of 5-HT released with each impulse (Anthony et al. 2000). Again, the decrease in mRNA production coincides temporally with the time frame for SSRI therapeutic

effects.

INDICATIONS AND EFFICACY

Sertraline is currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of major depressive disorder (MDD), obsessive-compulsive disorder (OCD) and pediatric OCD, posttraumatic stress disorder (PTSD), panic disorder, premenstrual dysphoric disorder (PMDD), and, most recently, social anxiety disorder. Some of the pivotal studies using this compound for these indications are reviewed below.

Major Depressive Disorder

The efficacy of sertraline in the treatment of MDD was established by a number of placebo-controlled trials for acute-phase therapy (Fabre et al. 1995; Opie et al. 1997; Reimherr et al. 1990). In a multicenter trial, 369 patients were randomly assigned to a fixed dose of sertraline (50 mg, 100 mg, or 200 mg daily) or placebo for 6 weeks (Fabre et al. 1995). Patients at all doses of sertraline showed approximately equivalent improvement, which was greater than placebo for most measures, including the total Hamilton Rating Scale for Depression (Ham-D) score, Beck subscale of the Ham-D, and the Clinical Global Impressions (CGI) Scale score. The combined effect size for sertraline, compared with placebo, was 0.31 (Davidson et al. 2002).

Sertraline was compared with amitriptyline and placebo in a multicenter trial of 448 patients (Reimherr et al. 1990). Sertraline was dosed flexibly up to 200 mg daily, and amitriptyline was administered at dosages as high as 150 mg/day. Both active treatments were superior to placebo, as indicated by Ham-D and CGI scores; similarly, response rates (rates at which patients attained a 50% decrease in the Ham-D or a CGI score of 1 or 2) were higher with the active treatment compared with placebo. Comparisons of sertraline and amitriptyline showed superiority on the Ham-D for amitriptyline until about week 3, after which both treatments were equivalent; response rates were nonsignificantly higher in the amitriptyline group. The effect size for sertraline, compared with placebo, in this study was 0.45 (Davidson et al. 2002).

A recent study sponsored by the National Institute of Mental Health (NIMH) that compared the acute-phase efficacy of *Hypericum perforatum* (St. John's wort), sertraline, and placebo in the acute-phase treatment of MDD had more equivocal results (Davidson et al. 2002). The study enrolled 340 patients with MDD for 8 weeks of treatment. Average patient age ranged from 40 to 43 years, and 37%–40% were male. The dosage of sertraline was flexibly titrated to 50–150 mg daily, although patients were at the highest dose for no more than 2 weeks. At study endpoint, there were no statistically significant differences in full response, defined as a CGI Scale score of ≤2 and a Ham-D score of ≤8. However, more patients had a partial response (CGI ≤2, 50% improvement on the Ham-D, but not full response) in the sertraline group (26%), compared with the placebo (13%) and *Hypericum* (16%) groups. Sertraline was also statistically superior to both placebo and *Hypericum* when the CGI Scale was used as a continuous measure. The effect size for sertraline, compared with placebo, was 0.24 with the Ham-D and 0.41 with the CGI Scale (Davidson et al. 2002). The difference between sertraline and placebo may have failed to achieve significance in some tests because the sample size may have been inadequate given the effect size.

In a multicenter study of 235 men and 400 women with either chronic MDD (enduring at least 2 years) or MDD superimposed on dysthymic disorder, probands were randomly assigned to 12 weeks of either sertraline or imipramine in a 2:1 ratio (Kornstein et al. 2000). Treatment was double-blind, and participants had their medication titrated to a maximum total daily dose of 200 mg of sertraline or 300 mg of imipramine. Full remission was defined as a CGI–Improvement (CGI-I) score of ≤2 and a 24-item Ham-D ($Ham\text{-}D_{24}$) score of <7; criteria for satisfactory response were a decrease in the $Ham\text{-}D_{24}$ to 50% of baseline, an absolute score of ≤15, a CGI–Severity of Illness (CGI-S) score of ≤3, and a CGI-I score of ≤2, but no full remission. Remission occurred in 36% and 40% of the sertraline

and the imipramine groups, respectively. Satisfactory response rates were 22% and 21% for the sertraline and the imipramine groups, respectively.

An interesting finding from this study is that men and women had differential response rates to sertraline and imipramine (Kornstein et al. 2000). The remission and satisfactory response groups were combined for this analysis. When these criteria and an intent-to-treat group were used, it was found that 57% of women, but only 46% of men, responded to sertraline. Response was somewhat better for imipramine, compared with sertraline, among men (62% for imipramine and 45% for sertraline). Response rates were more rapid for men assigned to imipramine and for women given sertraline and did not differ if only completers were used in the analysis. Premenopausal women were more likely to respond to sertraline, while postmenopausal women were equally likely to respond to either agent.

Sertraline has been shown to be effective for maintenance-phase treatment, generally in patients with MDD (Doogan and Caillard 1992) and in patients with chronic MDD (defined as MDD enduring at least 2 years or co-occurring with dysthymic disorder) (Keller et al. 1999). The Doogan and Caillard (1992) study included more than 450 patients with MDD (17-item Ham-D [Ham-D_{17}] >17) who entered 8 weeks of acute-phase treatment with sertraline, dosed flexibly between 50 and 200 mg daily; 68% of those patients responded, and 300 patients entered double-blind, placebo-controlled maintenance therapy. After 44 weeks of maintenance treatment, 13% of sertraline-treated patients, compared with 46% of placebo-treated patients, experienced a relapse.

The utility of sertraline in preventing illness recurrence has been explored using data from the chronic depression maintenance trial discussed above (Keller et al. 1999). Fifty-five percent of the acute-phase responders (378 of the total 426 patients who received sertraline) began continuation-phase treatment, and 169 patients continued to meet the criteria for remission (CGI-I score of 1 or 2 and a Ham-D score of <8); 161 patients entered maintenance treatment and were randomly assigned to 52 weeks of treatment with either placebo or a flexible dose of sertraline (maximum 200 mg daily). More than 60% of those entering maintenance treatment were female and had a current episode of depression that exceeded 8 years in duration. Sertraline significantly outperformed placebo for all outcome measures, which included the Ham-D, CGI Scale, Beck Depression Inventory (BDI), Cornell Dysthymia Scale, and Montgomery-Åsberg Depression Rating Scale; 20% of sertraline-treated patients and 50% of placebo-treated patients experienced illness recurrence.

In addition to the above trials, several studies found sertraline to be at least as effective as TCAs in treating younger adults (Cohn et al. 1990; Lydiard et al. 1997; Moller et al. 1998) and elderly patients (Bondareff et al. 2000; Finkel et al. 1999; Forlenza et al. 2001) with MDD. Sertraline has been shown to be as beneficial as nortriptyline in women with postpartum major depression (Wisner et al. 2006). Furthermore, sertraline may also confer a prophylactic advantage in women at high risk for developing postpartum depression (Wisner et al. 2004). Other trials show roughly equivalent response between sertraline and other SSRIs (Aguglia et al. 1993; Franchini et al. 1997; Nemeroff et al. 1996; Newhouse et al. 2000; Stahl 2000). A recent study suggests that the combination of liothyronine and sertraline enhances the antidepressant effect of the latter and leads to higher remission rates (Cooper-Kazaz et al. 2007).

Obsessive-Compulsive Disorder

Several multicenter trials find benefit of sertraline over placebo in the acute- and maintenance-phase treatment of OCD in adults. One earlier, smaller study failed to show superiority of sertraline over placebo, perhaps because of the limited sample size (n = 19) or the treatment-resistant characteristics of the cohort (Jenike et al. 1990). Larger-scale studies with diverse patients had differing results. In a 12-week flexible-dose study (Kronig et al. 1999), 167 patients were randomly

assigned to placebo or sertraline. Between 53% and 57% of the subjects were male, and the average age was 37–38 years. The mean daily dose of sertraline at endpoint was 165 mg (SD = 55 mg). By week 3, significant differences between drug and placebo emerged. Forty-one percent of patients receiving sertraline and 23% of patients receiving placebo achieved a CGI-I score of 1 or 2 at endpoint.

A fixed-dose study (Greist et al. 1995) also found superior results with three different doses of sertraline, compared with placebo, over 1 year. Three hundred twenty-five subjects with OCD from 11 sites were randomly assigned to 12 weeks of double-blind treatment with one of three fixed doses of sertraline (50, 100, or 200 mg) or placebo after a 1-week washout period. At the end of this period, all treatment responders were offered enrollment in an additional 40 weeks of treatment. Forty percent of sertraline responders versus 26% of placebo responders entered the second phase of the study, a significant difference ($P = 0.025$). In fact, over the full 52 weeks of the study, subjects treated with sertraline demonstrated significantly greater improvement than subjects given placebo, based on efficacy measures that included the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) ($F_{1,289} = 7.06$, $P = 0.001$), the NIMH–Global Obsessive-Compulsive Scale (NIMH-GOCS) ($F_{1,311} = 11.22$, $P = 0.0009$), the CGI Scale ($F_{1,311} = 8.09$, $P = 0.005$), and the CGI-I ($F_{1,311} = 7.18$, $P = 0.0007$).

Some evidence suggests that higher amounts of sertraline may be helpful for patients who fail to respond at standard dosages. In one study, 66 patients with OCD who failed to respond to sertraline therapy at doses of 200 mg/daily after 16 weeks of treatment were randomly assigned to continue on the same dose for an additional 12 weeks or to increase their dose to 250–400 mg/daily (Ninan et al. 2006). At the end of the trial, those receiving higher doses had greater improvement in Y-BOCS scores, though responder rates (at least a 25% decrease in Y-BOCS scores and a CGI-I rating ≤ 3) between the two groups were similar.

Other studies supporting the utility of sertraline in OCD include head-to-head comparison studies with other antidepressants (Bergeron et al. 2002; Bisserbe et al. 1995; Hoehn-Saric et al. 2000). In a comparison of lower-dose sertraline with cognitive-behavioral group therapy, both treatments were shown to be efficacious, though OCD patients treated with group therapy had greater reduction in symptoms (Sousa and Isolan 2006).

Pediatric Obsessive-Compulsive Disorder

Sertraline is approved for use in children for the treatment of OCD. In a 12-week double-blind, placebo-controlled, parallel-group, multicenter study, March et al. (1998) found that children and adolescents treated with sertraline showed significant improvement on several efficacy measures, compared with placebo. One hundred eighty-seven subjects (107 children, ages 6–12 years, and 80 adolescents, ages 13–17 years) were randomly assigned to receive either sertraline (92 subjects) or placebo (95 subjects). The mean dosage at endpoint was 167 mg/day for sertraline and 180 mg/day for placebo. Subjects who were treated with sertraline showed significantly greater improvement than placebo on the Y-BOCS (–6.8 and –3.4, respectively; $P = 0.005$), NIMH-GOCS (–2.2 and –1.3, respectively; $P = 0.02$), and CGI-I (2.7 and 3.3, respectively; $P = 0.002$). The authors reported a small number of dropouts because of adverse events and overall found sertraline to be a safe, well-tolerated treatment for this age group. In children and adolescents treated with sertraline over 12 months (at doses between 50–200 mg/daily over 52 weeks), evidence suggests that acute response can convert to full or partial remission of symptoms with longer-term treatment (Wagner et al. 2003).

Posttraumatic Stress Disorder

The efficacy of sertraline for the treatment of PTSD is supported by two large multicenter, acute-phase, double-blind, placebo-controlled studies (Brady et al. 2000; Davidson et al. 2001), a long-term treatment study (Londborg et al. 2001), and a relapse prevention trial (Davidson et al. 2001). In one

acute-phase trial (Davidson et al. 2001), 208 civilian patients were randomly assigned to either sertraline or placebo for 12 weeks of treatment. The symptom reductions with active treatment were about 50% for reexperiencing/intrusion, just under 50% for avoidance/numbing, and 40% for arousal. The probability of response, defined as a CGI Scale score of 1 or 2 and a minimal 30% decrease in the Clinician-Administered PTSD Scale—Part 2 (CAPS-2), was 0.65 in sertraline-treated patients and 0.38 in placebo-treated patients at 12 weeks. Approximately 40% of each group had comorbid MDD, and baseline 21-item Ham-D scores were around 21. Of interest, there were no significant differences among groups in this depression measure at 12 weeks, suggesting that depression in the context of PTSD may be more treatment refractory. An acute-phase study by Brady et al. (2000) had similar results. Although both studies concluded that sertraline was a well-tolerated and effective treatment for PTSD, findings from a recent Department of Veterans Affairs (VA) medical center study failed to show that sertraline was more efficacious than placebo in patients with predominantly combat-related PTSD (Friedman et al. 2007). It has been proposed that patients in VA settings may constitute a special population with particularly treatment-refractory PTSD.

The acute-phase efficacy of sertraline in treating PTSD in the studies reviewed above (Brady et al. 2000; Davidson et al. 2001) was significant for women; however, it failed to achieve significance, compared with placebo, for men. Some research suggests treatment efficacy may vary between men and women and the type of traumas experienced. Other research has shown no significant gender differences in patients with combat-related PTSD in response to sertraline (Friedman et al. 2007). The overall sex difference in response is not attributable to inclusion of studies with "treatment-resistant" male VA patients, because the lack of difference occurred with civilian males. Reasons for the sex difference in efficacy findings are not clear. One possible explanation is that women are more likely to experience sexual or physical trauma and childhood abuse than men, and perhaps the nature of the trauma itself may alter response to medication (Stein et al. 2006). However, it is intriguing that, compared with men, women appeared to have a superior response to sertraline in the chronic depression study reviewed above.

The long-term benefit of sertraline in the treatment of PTSD has also been shown in a study by Londborg et al. (2001). Subjects who had completed 12 weeks of double-blind, placebo-controlled acute-phase treatment for PTSD with sertraline (Brady et al. 2000) were eligible for enrollment in a 24-week open-label continuation study (Londborg et al. 2001). This study, which included 252 patients, found that 92% of those who responded to acute-phase treatment with sertraline sustained their response over 36 weeks. Furthermore, 54% of patients with minimal acute-phase response went on to respond during the subsequent continuation of treatment. Londborg et al. (2001) found that about 20%–25% of the total improvement in PTSD symptoms seen over the full 36 weeks of treatment occurred during the continuation phase (weeks 12–36). The greatest improvement over time was among patients who were originally considered "nonresponders" in the acute phase. On the basis of these data, the authors concluded that as many as one-third of PTSD patients may require longer treatment to achieve a clinically significant response.

Davidson et al. (2001) furthered the aforementioned work by examining the efficacy of sertraline in maintaining improvement in PTSD symptoms, as well as in preventing the relapse of these symptoms, in a 28-week double-blind continuation study. Ninety-six patients were randomly assigned to receive either sertraline or placebo. At the end of the study, sertraline was found to be significantly superior to placebo in preventing relapse of PTSD, as defined by three primary outcome measures: relapse (sertraline vs. placebo, 5.3% and 26.1%, respectively; $P < 0.02$), relapse or discontinuation due to clinical deterioration (sertraline vs. placebo, 15.8% and 45.7%, respectively; $P = 0.005$), and acute exacerbation (sertraline vs. placebo, 15.8% and 52.2%, respectively; $P < 0.001$). Relative risk of relapse (RR) after discontinuing sertraline was 6.35. Other outcomes were relapse or discontinuation due to clinical deterioration (RR = 4.48 for patients switched to placebo, compared with those maintained on sertraline) and acute exacerbation of symptoms (RR = 5.82 of placebo over sertraline).

On measures of symptom severity, patients who were treated with sertraline demonstrated changes on their scores on the Davidson Trauma Scale ($P = 0.008$), Impact of Event Scale ($P < 0.03$), and CGI-S ($P = 0.002$), compared with placebo subjects.

Panic Disorder

Sertraline has also proven effective in the treatment of panic disorder, as demonstrated by a number of studies. In a 12-week randomized, placebo-controlled, flexible-dose multicenter study of outpatients with panic disorder (with and without agoraphobia) but without depression (Pohl et al. 1998), sertraline was superior to placebo on a number of efficacy measures. One hundred sixty-eight patients meeting DSM-III-R (American Psychiatric Association 1987) criteria for panic disorder without depression were randomly assigned to receive sertraline (80 patients) or placebo (88 patients) after a 2-week single-blind lead-in. Mean dosage at endpoint for sertraline-treated patients was 126 mg/day (SD = 62 mg/day), and the reduction in frequency of panic attacks was significantly greater for those treated with sertraline compared with those on placebo (77% vs. 51%, respectively). The mean number of limited-symptom attacks for the sertraline group also decreased significantly more than for those given placebo (5.9 [SD = 8.8] and 2.4 [SD = 7.0], respectively). Other outcomes that reached statistical significance included scores on the CGI-S ($F_{1,145} = 13.35$, $P < 0.001$) and CGI-I ($F_{1,146} = 15.83$, $P < 0.001$) Scales, as well as ratings on the Quality of Life Enjoyment and Satisfaction Questionnaire ($F_{1,125} = 7.94$, $P = 0.006$). Similar results were reported by Pollack et al. (1998), who randomly assigned 178 patients to sertraline or placebo.

A fixed-dose study employed 50 mg, 100 mg, or 200 mg of sertraline or placebo for 12 weeks (Londborg et al. 1998). Outcomes, including number of panic attacks and limited-symptom attacks, severity of anticipatory anxiety, dimensional anxiety measures, and global measures of improvement, showed that sertraline, at all doses, was significantly superior to placebo. Pooled sertraline data indicated a 65% reduction in the number of panic attacks, compared with a 39% decrease in the placebo group. Effect sizes, or the magnitude of difference between the two treatments, for the three doses were 0.58 (50 mg), 0.41 (100 mg), and 0.60 (200 mg). Response rates did not differ significantly between fixed-dose groups. In the above panic studies, the authors reported a low incidence of attrition secondary to sertraline adverse events, concluding that sertraline is a safe, as well as effective, treatment for patients with panic disorder.

Premenstrual Dysphoric Disorder

In one of the first multicenter trials to test the efficacy of an antidepressant agent for PMDD, sertraline was compared with placebo (Yonkers et al. 1997). Either placebo or sertraline, administered flexibly and daily, was given to 243 women. After three menstrual cycles of treatment, total daily rating scores had decreased by 32% and 11% in the sertraline- and placebo-treated groups, respectively. Both emotional and physical symptom clusters had improved by 32% with sertraline treatment, a reduction that was about threefold higher than the change seen with placebo. At the endpoint, CGI-I scores of 1 or 2 were achieved by 62% and 34% of those assigned to sertraline and placebo, respectively.

In a second multicenter trial, it was shown that sertraline treatment could be commenced halfway through the menstrual cycle (i.e., at ovulation) and still be more effective than placebo (Halbreich et al. 2002). In this three-cycle flexible-dose study, 281 women were randomly assigned to receive total daily doses of 50–100 mg of sertraline or placebo. The responder rates in this study, after three cycles of luteal-phase treatment, were 50% and 26% for sertraline and placebo, respectively. As with the daily treatment study, improvement in functional impairment paralleled symptomatic improvement. Only 8% of the women taking sertraline and 1% of the women receiving placebo discontinued the study because of side effects. The efficacy of this platform of drug administration for women with PMDD potentially revolutionizes treatment approaches because many women with PMDD prefer to avoid taking medication during nonsymptomatic periods.

Social Anxiety Disorder

Several studies have established the efficacy of sertraline in the treatment of social anxiety disorder (also known as social phobia). In one of the earliest studies, sertraline treatment (at flexible doses of 50–100 mg/day) showed a statistically significant improvement compared with placebo, as measured by the Liebowitz Social Anxiety Scale (LSAS) (Katzelnick et al. 1995). A large double-blind, placebo-controlled study followed more than 200 Canadian outpatients with generalized social phobia for 20 weeks, measuring response on CGI-I scores and mean reductions on the social phobia subscale of the Marks Fear Questionnaire and the Brief Social Phobia scale (Van Ameringen et al. 2001). Fifty-three percent of patients treated with sertraline, compared with only 29% of patients receiving placebo, were either much or very much improved by the study's end, as measured by CGI-I scores. Statistically significant changes favoring sertraline were seen on the other two study measures as well. When subjects who responded to sertraline were randomly assigned to continue sertraline or switch to placebo for an additional 24 weeks, the relative risk of relapse for those who were randomized to placebo was greater than 10 (Walker et al. 2000).

Liebowitz et al. (2003) demonstrated that sertraline caused a significant reduction in LSAS scores and produced a greater proportion of responders after 12 weeks of treatment (at doses up to 200 mg/daily) compared to placebo. In a placebo-controlled study comparing sertraline, exposure therapy, or combined treatment involving over 380 Norwegian patients with generalized social phobia in general practices, sertraline alone or in combination with exposure therapy yielded statistically significant improvements in CGI social phobia scores, whereas exposure therapy alone did not (Blomhoff et al. 2001). Additional studies have commented on the efficacy of sertraline in the treatment of social phobia in adults (Czepowicz et al. 1995; Munjack et al. 1995; Roberts et al. 1995). While not FDA approved in the pediatric population, sertraline has been well tolerated and has shown efficacy in childhood social anxiety disorder (Compton et al. 2001).

Off-Label Use

Sertraline has also been studied for off-label use in the treatment of a variety of disorders. Sertraline has been used in a number of studies for treatment of a wide range of neurological conditions, including Alzheimer's dementia (Lyketsos et al. 2000; Magai et al. 2000; Volicer et al. 1994), depression associated with Parkinson's disease (Antonini et al. 2006; Hauser and Zesiewicz 1997; Meara and Hobson 1998), and depression-linked fatigue in multiple sclerosis (Mohr et al. 2003).

Sertraline has also demonstrated success in the treatment of depression in patients with schizophrenia (Addington et al. 2002; Kirli and Caliskan 1998; Mulholland et al. 2003). Several studies have established the benefit of sertraline in generalized anxiety disorder (GAD). Two randomized trials showed the superiority of sertraline over placebo (Allgulander et al. 2004; Brawman-Mintzer et al. 2006) and similar efficacy as paroxetine (Ball et al. 2005) in GAD. Sertraline has been studied for use in a number of impulse-control disorders, with mixed results. In combination with habit reversal training, sertraline has been utilized in the treatment of trichotillomania, with good outcomes (Dougherty et al. 2006). However, a trial of sertraline in patients with pathological gambling did not show any superiority in control of gambling behaviors compared with placebo (Saiz-Ruiz et al. 2005). Some studies suggest a role for sertraline in the treatment of several types of eating disorders, including anorexia nervosa (Santonastaso et al. 2001), bulimia nervosa (Milano et al. 2004), binge-eating disorder (Leombruni et al. 2006; McElroy el al. 2000), and night-eating syndrome (O'Reardon et al. 2006).

There have been a limited number of studies examining the potential for sertraline in substance use disorders. Trials of sertraline in alcohol (Kranzler et al. 2006), methamphetamine (Shoptaw et al. 2006), and cocaine dependence (Winhusen et al. 2005) do not suggest any benefit in helping curb substance abuse.

In a placebo-controlled trial (Rynn et al. 2001), sertraline was both effective and safe in children with GAD. Sertraline has also been used successfully in the treatment of children and adolescents with major depression and dysthymic disorder (Ambrosini et al. 1999; Nixon et al. 2001). Pervasive developmental disorder has been successfully treated with sertraline, according to at least two studies (Hellings et al. 1996; McDougle et al. 1998).

Sertraline is one of the few antidepressants that has been shown to be safe and effective for the treatment of depression in patients with cardiovascular disease. In a well-publicized study by the Sertraline Antidepressant Heart Attack Randomized Trial (SADHART) Group, 369 patients with a recent myocardial infarction or hospitalization for unstable angina who also met criteria for a current major depressive episode were randomly assigned to sertraline (at flexible dosages of 50–200 mg/daily) or placebo for 24 weeks (Glassman et al. 2002). The main outcome measure was change from baseline left ventricular ejection fraction (LVEF) and secondary measures included scores on the Ham-D and CGI-I Scale. Not only was there no statistical difference in LVEF between the two patient groups, but patients treated with sertraline had fewer severe cardiovascular events (though this did not reach statistical significance). Sertraline was also superior to placebo in improving CGI scores, though no significant difference was seen in Ham-D scores. In a separate analysis of the SADHART data, patients treated with sertraline experienced fewer psychiatric or cardiovascular hospitalizations during the treatment period (O'Connor et al. 2005).

While the mechanism of cardiovascular benefit is not entirely clear, sertraline may decrease platelet adherence, thus decreasing the likelihood of recurrent myocardial events (McFarlane et al. 2001; Shapiro et al. 1999). Sertraline has also been shown to improve quality-of-life measurements in depressed patients with acute coronary syndrome (Swenson et al. 2003) and stroke (Murray et al. 2005).

Sertraline has been studied in patients with cancer who do not have MDD, but have some symptoms of the disorder. In a double-blind, controlled trial of almost 200 patients with advanced disease, Stockler et al. (2007) showed that sertraline had no benefit over placebo in ameliorating depression, anxiety, fatigue, or sense of well-being after 8 weeks of treatment.

TCAs have long been used for their analgesic properties, though side effects can sometimes impair efficacy. A 10-week study of sertraline in 50 patients with chronic tension headaches showed a decline in analgesic medication use, suggesting sertraline may be a good alternative for patients who cannot tolerate the adverse events associated with TCAs (Singh and Misra 2002).

Several studies have used sertraline to treat the side effect of premature ejaculation (Arafa and Shamloul 2006; Balbay et al. 1998; Biri et al. 1998; McMahon 1998; Mendels et al. 1995). The side effect of sexual dysfunction associated with the medication may underlie the success found by these investigators.

A number of studies have highlighted the effective use of sertraline in treating aggressive behaviors (Buck 1995; Feder 1999), specifically in patients with personality disorders (Kavoussi et al. 1994) and Huntington's disease (Ranen et al. 1996).

Sertraline has been used to improve pathological crying and pseudobulbar-type affects (Benedek and Peterson 1995; Mukand et al. 1996; Okun et al. 2001; Peterson et al. 1996).

In at least two studies, sertraline has been shown to be effective in preventing dialysis-induced hypotension, a condition that can be exacerbated by other antidepressive agents (Dheenan et al. 1998). Sertraline has also been used to treat pruritus associated with cholestatic liver disease (Mayo et al. 2007) and severe, refractory tinnitus (Zoger at al. 2006).

Another proposed off-label use for sertraline is the alleviation of hot flashes associated with menopause (Gordon et al. 2006; Grady et al. 2007; Plouffe et al. 1997) and tamoxifen treatment for

breast cancer (Kimmick et al. 2006) in women and in men following medical castration for advanced prostate cancer (Roth and Scher 1998), suggesting that 5-HT may play a role in vasomotor instability associated with hormonal changes. One study suggested that response to sertraline in hot flashes is related to activity level, education, and menopausal status (Kerwin et al. 2007).

SIDE EFFECTS AND TOXICOLOGY

Sertraline has been demonstrated to have a low incidence of anticholinergic, sedative, or cardiovascular effects because of its low affinity for adrenergic, cholinergic, histaminergic, or benzodiazepine receptors. However, sertraline was associated with a number of adverse effects in premarketing evaluation, the most common of which included gastrointestinal disturbance (nausea, 27%; diarrhea/loose stools, 21%), sleep disturbance (insomnia, 22%; somnolence, 14%), headache (26%), dry mouth (15%), and sexual dysfunction (ejaculation failure, 14%; decreased libido, 6%). Other side effects reported by subjects, described as frequent (i.e., they occurred in at least 1 of 100 subjects) in premarketing pooled data from clinical trials, include impotence, palpitations, chest pain, hypertonia, hypoesthesia, increased appetite, back pain, asthenia, malaise, weight gain, myalgia, yawning, rhinitis, and tinnitus ("Zoloft" 2001).

Since sertraline has been approved for use, there have been a number of reports of different adverse events associated with its use. Sertraline and other SSRIs have been associated with instances of hyponatremia, as well as with the syndrome of inappropriate antidiuretic hormone (SIADH) secretion (see Bouman et al. 1997; Bradley et al. 1996; Catalano et al. 1996; Goldstein et al. 1996; Kessler and Samuels 1996). Bradley et al. (1996), in a review of the literature, noted that the average age of patients experiencing SIADH is over 70 years, suggesting that the elderly may be more vulnerable to age-related changes in water balance, which may make them more susceptible to developing SIADH with an SSRI. Furthermore, the authors suggested that sertraline may have some effect on vasopressin secretion, although they stated that there have been no controlled studies to confirm this link.

Extrapyramidal side effects (EPS), including dyskinesias, dystonias, and akathisia, have also been seen with sertraline use, although they are infrequent (Altshuler and Szuba 1994; Lambert et al. 1998; Madhusoodanan and Brenner 1997; Opler 1994). Hamilton and Opler (1992) suggested that the underlying mechanism of SSRI-induced akathisia is serotonergic inhibition of the nigrostriatal DA pathway, which can be associated with parkinsonism (Leo et al. 1995; Pina Latorre et al. 2001). Madhusoodanan and Brenner (1997), in a case report of choreiform dyskinesia and EPS associated with sertraline therapy, proposed that 5-HT-driven antagonism of dopaminergic transmission in the nigrostriatal pathway, as well as in the ventral tegmental area (VTA), may be responsible for the development of EPS.

Sexual side effects are a well-known side effect of SSRIs, including sertraline. A recent Cochrane Database review noted that while there is currently limited evidence available, some trials suggest that the addition of sildenafil or bupropion can reduce antidepressant-induced erectile dysfunction in men (Rudkin et al. 2004).

Other adverse events associated with sertraline are rare and include seizures (Raju et al. 2000; Saraf and Schrader 1999), stuttering (Brewerton et al. 1996; Christensen et al. 1996; McCall 1994), altered platelet function and bleeding time (Calhoun and Calhoun 1996; Mendelson 2001), and galactorrhea (Bronzo and Stahl 1993; Lesaca 1996). A recent study of children and adolescents with epilepsy and depression demonstrated sertraline's efficacy in treating depressive symptoms while maintaining good seizure control (Thome-Souza et al. 2007). Urinary hesitancy and retention have been reported in a few cases in women (Lowenstein et al. 2007).

As with all other antidepressants, sertraline carries an FDA black box warning regarding increased risk of suicidality in children and adolescents. Interestingly, one study of suicidal thinking and

behavior in more than 700 seniors with late-life depression showed no increase in suicidality in those treated with sertraline versus placebo (Nelson et al. 2007).

Sertraline has also been associated with a discontinuation syndrome. Leiter et al. (1995) described two cases in which patients experienced a constellation of symptoms, including alterations in mood, cognition, energy, gait, and equilibrium, in addition to gastrointestinal symptoms, headaches, and paresthesias. Elsewhere there have been reports of insomnia, impaired short-term memory, myalgias, dyspnea, and chills without fevers (Louie et al. 1994). On the other hand, in a systematic 28-week study involving panic disorder patients (Rapaport et al. 2001), abrupt discontinuation of sertraline was primarily associated only with insomnia (15.7% of patients randomly assigned to placebo vs. 4.3% continuing on sertraline) and dizziness (4.3% of patients continuing to take sertraline and 16.4% switched to placebo). There was no statistically significant deterioration in headache or in general malaise.

DRUG–DRUG INTERACTIONS

Sertraline has a number of drug–drug interactions of which clinicians need to be aware. Because the drug is tightly bound to plasma proteins, caution should be employed when sertraline is used in combination with pharmaceuticals possessing similar characteristics, such as warfarin, and prothrombin time should be monitored when sertraline and warfarin are used concurrently ("Zoloft" 2001). The potential for serotonin syndrome may be increased when sertraline is combined with other SSRIs, serotonin–norepinephrine reuptake inhibitors, or triptans used for the acute treatment of migraines. The administration of sertraline and MAOIs is contraindicated because of the significant risk of serotonin syndrome with this combination.

As discussed earlier, sertraline inhibits a number of enzymes in the cytochrome P450 system, most significantly CYP2D6. However, the degree of inhibition is relatively minor in comparison with other SSRIs, such as fluoxetine and paroxetine (Preskorn et al. 2007). Because TCAs are substrates of CYP2D6, drug levels and dosages need to be closely monitored when TCAs are used in combination with sertraline.

CONCLUSION

Controlled clinical trials support the efficacy of sertraline in the treatment of a variety of disorders, including mood disorders, such as MDD and PMDD, and anxiety disorders, such as OCD, PTSD, and social phobia. It may be that response is somewhat more favorable in younger women with mood disorders, perhaps because women are more likely to have anxious symptoms. Uncontrolled studies suggest an expanded role for sertraline in a variety of other conditions that require further evaluation. The safety profile is superior to that of the older antidepressant agents, thus increasing the potential target population of patients with mood and anxiety disorders.

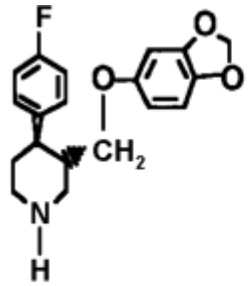
Chapter 15. Paroxetine

PAROXETINE: INTRODUCTION

Paroxetine (Paxil) is classified as one of the serotonin reuptake inhibitors (SRIs) because of its potent inhibition of presynaptic serotonin (5-HT) uptake. It is also a relatively potent norepinephrine (NE) reuptake inhibitor, particularly at higher doses, leading some to argue for its inclusion in the growing class of acknowledged dual serotonin–norepinephrine reuptake inhibitors (SNRIs). Since its approval for the treatment of depression, paroxetine has been demonstrated to be effective and has been approved for a broad spectrum of anxiety disorders, including panic disorder, obsessive-compulsive disorder (OCD), social anxiety disorder, generalized anxiety disorder (GAD), and posttraumatic stress disorder (PTSD). Moreover, studies have demonstrated the efficacy of paroxetine in premenstrual dysphoric disorder (PMDD), postmenopausal hot flashes, and child and adolescent OCD and social anxiety disorder. Paroxetine is still one of the most prescribed antidepressant medications in the United States because of its proven efficacy, as demonstrated in randomized, double-blind clinical trials, and its much improved tolerability compared with tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). Although paroxetine shares many characteristics with other members of the SRI class, its unique pharmacological characteristics and clinical database are reviewed, with particular attention to the clinical setting.

HISTORY AND DISCOVERY

The synthesis of the first SRI, fluoxetine, in 1972 marked the inception of an exciting new era of scientific and clinical innovation in the field of psychiatry (Wong et al. 1995). Prior to this discovery, psychiatrists had only a few classes of pharmacological treatments for managing depression and anxiety. These medications, including TCAs, MAOIs, and benzodiazepines, were indeed efficacious; however, they were poorly tolerated and, therefore, quite limited in usefulness.



Shortly after the introduction of fluoxetine into the U.S. market in 1988, a marked increase in research led to the development of other SRIs, which ultimately proved effective in a wide array of psychiatric disorders. Paroxetine was the third SRI approved by the U.S. Food and Drug Administration (FDA) for the treatment of depression. Since then, it has also attained approval by the FDA for the treatment of all five DSM-IV-TR (American Psychiatric Association 2000) anxiety disorders: panic disorder, OCD, PTSD, social anxiety disorder, and GAD. Paroxetine is available in 10-, 20-, 30-, and 40-mg tablets and in suspension form. A controlled-release (CR) formulation is available in 12.5-, 25-, and 37.5-mg tablets. It exhibits equal or better efficacy than the paroxetine immediate-release (IR) formulation, as well as clear advantages in tolerability (Golden et al. 2002).

STRUCTURE–ACTIVITY RELATIONS AND PHARMACOLOGICAL PROFILE

Paroxetine is a phenylpiperidine derivative chemically unrelated to any other antidepressant (Bourin et al. 2001) (Figure 15–1). As noted above, it has been traditionally codified with the SRI class of drugs and is indeed the most potent inhibitor of the serotonin transporter (5-HTT) within this group of compounds (Frazer 2001). By comparison, sertraline has about one-half and fluoxetine has only one-tenth the affinity of paroxetine for the human 5 HTT (Owens et al. 1997). Positron emission tomography (PET) reveals that 85%–100% of 5-HTT binding sites are occupied in the amygdala and midbrain following 20- to 40-mg daily doses of paroxetine in human subjects (Kent et al. 2002; Meyer

et al. 2001). Paroxetine-induced antagonism of the 5-HTT is prolonged following single-dose administration, and transporter binding is maintained for up to 14 days after 4 weeks of treatment in rodents, suggesting that it dissociates slowly from the 5-HTT binding site (Magnussen et al. 1982; Thomas et al. 1987).

Data from both humans and rodents, using the transfected human norepinephrine transporter (NET), have revealed that paroxetine is the most potent inhibitor of the NET among drugs classified as SRIs. Despite its relatively high affinity for the NET, paroxetine has a higher affinity for the 5-HTT (Finley 1994). Ex vivo experiments in rats demonstrated a 21% and 34% inhibition of the NET within the central nervous system (CNS) at serum concentrations of 100–500 ng/mL and >500 ng/mL, respectively (Owens et al. 2000). Results from an ex vivo study of patients with depression demonstrated substantial NET antagonism at serum concentrations attained with paroxetine IR dosages of 40 mg/day and higher (Gilmor et al. 2002) (Figure 15–2). These results have recently been replicated in depressed patients in a high-dose, forced-titration protocol comparing paroxetine CR dosages of 12.5 and 75 mg/day with venlafaxine XR dosages of 75–375 mg/day. Both medications produced dose-dependent inhibition of the 5-HTT and NET. Maximal 5-HTT inhibition for paroxetine and venlafaxine was 90% and 85%, respectively, whereas maximal NET inhibition for the two drugs was 33% and 61% (Owens et al. 2008). Such data reflect the inhibitory activity of both medications at the NET and 5-HTT within the CNS. The utility of ex vivo studies is best understood with respect to bioavailability. Paroxetine, which is highly protein bound, must pass through the blood–brain barrier in order to interact with the NET and thereby contribute to the antidepressant effect of the drug (Frazer 2001). Because the ex vivo studies utilize transfected cells in tissue culture exposed to patient sera, only free drug that is not protein bound is available to interact in the NE uptake assay. These results can therefore be extrapolated to pharmacological effects in the CNS. Whether the NET antagonism observed in these ex vivo studies has clinical significance in terms of additional efficacy in comparison with drugs that solely block 5-HT reuptake will need to be further studied.

Standard curves for paroxetine inhibition of NE **(A)** and 5-HT **(B)** resulting from NET and 5-HTT antagonism, respectively. Note that at 100 ng/mL of paroxetine, which represents a typical therapeutic dose, there is a 15% decrease in NE uptake and a 90% decrease in 5-HT uptake. Transporter inhibition occurs in a dose-dependent manner. 5-HT = serotonin; 5-HTT = serotonin transporter; NE = norepinephrine; NET = norepinephrine transporter.

Paroxetine's role as a norepinephrine reuptake inhibitor (NRI) has implications for interpreting the results of head-to-head comparisons with other antidepressants. The minimal NET activity observed at more conventional doses of paroxetine necessitates that clinical trials comparing it with established SNRIs (Goldstein et al. 2004; Shelton et al. 2005) would have to employ doses much higher than 20 mg in order to be considered a valid comparison. It currently remains somewhat controversial whether the combination of 5-HTT and NET inhibition is associated with greater antidepressant efficacy (J. C. Nelson 1998; J. C. Nelson et al. 1991, 2004; Seth et al. 1992; Thase et al. 2001). Additionally, it remains to be discovered what magnitude of NE reuptake inhibition would result in increased efficacy and/or decreased latency of antidepressant effect.

Paroxetine has no appreciable affinity for the dopamine transporter (DAT) or for dopamine$_1$ (D_1), dopamine$_2$ (D_2), serotonin$_{1A}$ (5-HT_{1A}), serotonin$_{2A}$ (5-HT_{2A}), α_1- and α_2-adrenergic, and histamine$_1$ (H_1) receptors, indicating that it is a relatively "clean" drug, particularly when compared with the older generation of antidepressants, such as TCAs and MAOIs (Hyttel 1994; Owens et al. 1997). It is distinguished from sertraline by its high affinity for the NET and low affinity for the DAT. Sertraline, in contrast, has a very high affinity for the DAT but no affinity for the NET (Tulloch and Johnson 1992). The affinity of paroxetine for the muscarinic cholinergic receptor is approximately 22 nmol, which is

similar to that of desipramine, though paroxetine is used in lower doses than desipramine and is therefore less anticholinergic than this TCA. However, this property may account for its mild anticholinergic side effects, including dry mouth, blurry vision, and constipation (Owens et al. 1997). However, compared with nortriptyline, paroxetine has virtually no measurable anticholinergic activity in geriatric patients treated for depression (Pollock et al. 1998). Table 15–1 shows a comparison of paroxetine and other available antidepressants in terms of their affinity for various neurotransmitter receptors and monoamine transporters.

PHARMACOKINETICS AND DISPOSITION

Paroxetine is well absorbed from the alimentary tract, and absorption is not affected by the presence or absence of food (Kaye et al. 1989). Being a highly lipophilic compound, paroxetine is readily distributed into peripheral tissues and exhibits a high volume of distribution, ranging from 3.1 to 28 L/kg (Kaye et al. 1989). Once absorbed, paroxetine is reportedly 95% bound to serum proteins (Kaye et al. 1989), though we have observed protein binding of 85% in our studies (M. J. Owens and C. B. Nemeroff, unpublished observations, June 1997). Oral bioavailability is affected by extensive first-pass metabolism, which is carried out by a high-affinity, low-capacity hepatic enzyme system (Lane 1996). With serial dosing, bioavailability increases as this metabolic system becomes saturated and a larger proportion of parent compound enters the systemic circulation (Kaye et al. 1989). Steady-state concentrations of paroxetine, following oral dosing, exhibit wide intersubject variability (Sindrup et al. 1992a). Following 30 days of daily administration of 30 mg of paroxetine, steady-state plasma concentrations ranged from 8.6 to 105 ng/mL (Kaye et al. 1989). Such variability has been considered inconsequential because a consistent relationship between paroxetine levels and clinical response or adverse outcome has not been found (see Tasker et al. 1989). However, higher plasma concentrations are associated with a greater magnitude of both 5 HTT and NET inhibition (Gilmor et al. 2002).

Strong in vivo and in vitro evidence points to the hepatic cytochrome P450 (CYP) 2D6 enzyme system as the rate-limiting mechanism in the metabolism of paroxetine (Crewe et al. 1992; Sindrup et al. 1992a). Genetic studies have demonstrated up to 40 polymorphisms of the 2D6 enzyme, which likely explain, at least in part, the wide-ranging differences in pharmacokinetic parameters observed among individuals (Lane 1996). Phenotypically, individual probands can be categorized as poor, extensive, or

ultrarapid metabolizers and will have very high, low, or very low serum paroxetine concentrations, respectively (Charlier et al. 2003). Patients with negligible or diminished 2D6 activity are poor metabolizers of paroxetine and other 2D6-dependent substrates and are thought to use alternative enzyme systems (Gunasekara et al. 1998; Lane 1996). The 2D6 enzyme system is believed to be primarily responsible for the initial step in the metabolism of paroxetine in extensive and ultrarapid metabolizers, carrying out oxidation of the methylenedioxy bridge. The resulting unstable catechol intermediate is methylated and subsequently conjugated into polar compounds by the addition of a glucuronide or sulfate moiety and is then excreted into urine and feces (Haddock et al. 1989). These conjugated entities are the major circulating metabolites of paroxetine; however, unlike the metabolites of other SRIs, such as fluoxetine or sertraline, they exhibit minimal in vitro monoamine uptake inhibition and likely do not contribute any therapeutic activity (DeVane 1992; Haddock et al. 1989).

Paroxetine is the most potent inhibitor of the 2D6 enzyme system of all of the SRIs (K_i = 0.15 μM) (Crewe et al. 1992; Nemeroff et al. 1996). Studies in healthy volunteers show that the drug continues to cause meaningful inhibition of 2D6 up to 5 days postdiscontinuation (Liston et al. 2002). As both a substrate for and an inhibitor of its own metabolism, paroxetine has a nonlinear pharmacokinetic profile, such that higher doses produce disproportionately greater plasma drug concentrations as the enzyme becomes saturated and, therefore, less available for metabolic activity (Preskorn 1993). Peak plasma concentration is attained in approximately 5 hours, and plasma steady-state concentration is achieved within 4–14 days, following oral administration of paroxetine IR (Kaye et al. 1989). The terminal half-life ($t_{½}$) of the parent compound is approximately 1 day and increases at higher doses, consequent to autoinhibition of 2D6 (Preskorn 1993). The pharmacokinetic properties of paroxetine appear to be affected by age. Bayer et al. (1989) reported a threefold increase in maximum plasma concentration in elderly subjects, compared with younger subjects, following a single dose of paroxetine. Furthermore, $t_{½}$ in the elderly subgroup was extended by nearly 100%. Although there was significant overlap in both pharmacokinetic parameters between the age groups studied, the clinical principle of "start low and go slow" regarding medication treatment in older patients applies to paroxetine.

Patients with renal and hepatic insufficiency are often subject to alterations in metabolism and clearance of drugs, compared with healthy subjects. In individuals with renal impairment, both half-life and maximum plasma levels of paroxetine have been shown to increase relative to the extent of renal disease (Doyle et al. 1989). In a single-dose study, no significant difference was observed in pharmacokinetic outcomes in patients with cirrhosis of the liver, compared with healthy volunteers (Krastev et al. 1989); however, subsequent data revealed considerable elevations in steady-state concentration and $t_{½}$ of paroxetine following 14 days of administration of paroxetine in individuals with severe liver disease (Dalhoff et al. 1991). Accordingly, patients with substantial renal or hepatic dysfunction should initially be treated with a lower dose of paroxetine than is generally recommended to avoid potential side effects associated with unusually high plasma paroxetine levels.

Paroxetine CR was designed to slow absorption and delay the release of paroxetine until after the tablet has passed the stomach. The dissolution rate of paroxetine CR after single dosing is about 4–5 hours. It is completely absorbed and otherwise exhibits the same pharmacokinetic parameters with regard to $t_{½}$ and nonlinearity as the IR formulation. Following absorption, paroxetine CR is extensively distributed and highly protein bound. Paroxetine CR causes increased plasma concentrations of paroxetine in patients with renal and hepatic dysfunction, and lower doses are therefore recommended for these patients (Paxil CR 2002).

Paroxetine mesylate is a generic formulation of the compound in which a methanesulfonic acid moiety is attached to the compound during the salification process instead of the hydrochloric acid used in paroxetine hydrochloride. It is currently available in some European countries including Holland and

Denmark. Although currently there are no studies available comparing its efficacy or bioequivalence to paroxetine hydrochloride, there are several published case reports indicating problems of efficacy and tolerability in patients switched from paroxetine hydrochloride to paroxetine mesylate (Borgherini 2003) and this warrants further investigation.

PHARMACOGENOMICS

The subject of pharmacogenomics has been of increasing interest to researchers and clinicians in all branches of contemporary medicine, including psychiatry. Inquiries into this field have been undertaken to gain a better understanding of the mechanisms by which variation between individuals occurs in clinical response to psychopharmacological treatment. Although pharmacogenetic principles are covered more thoroughly elsewhere in this text (see Chapter 3, "Genetics and Genomics"), here we will briefly focus on some of the recent work as applied to paroxetine. Specific attention will be paid to aspects of drug–gene interactions that affect tolerance and efficacy.

As previously described in this chapter, paroxetine's primary mode of action is likely mediated by its binding to the serotonin transporter (5-HTT). A well-known polymorphism (5-HT transporter gene–linked polymorphic region [5-HTTLPR]) has been located in the promoter region of the gene (SLC6A4) that encodes 5-HTT, resulting in two alleles referred to as "long" and "short." It has been proposed that this polymorphism might be a pharmacogenetic marker for antidepressant efficacy with some evidence that the short form, or S allele, results in reduced efficacy to SRI medications, including paroxetine (Zanardi et al. 2000). This finding was replicated in a study that included severity of drug-induced adverse events, dosing compliance indices, and discontinuations due to adverse events as main outcome measures in elderly depressed patients treated with paroxetine. The data revealed that subjects carrying the S allele experienced more severe adverse events, achieved lower final daily doses, and had more discontinuations during the course of the study. When, however, these subjects reached doses comparable with those of the homozygous L/L sample, efficacy measures were quite similar, albeit slower to exert maximal benefit, indicating that the main effect of the S allele was on the tolerability of paroxetine rather than its efficacy (G. M. Murphy et al. 2004). In the only known head-to-head comparison of paroxetine and another SRI, in regard to the 5-HTTLPR polymorphism, a sample of 81 depressed Japanese patients were treated with either paroxetine or fluvoxamine. The results showed that although both drugs had similar efficacy in L-carrying probands, S/S homozygotes responded significantly better to paroxetine (Kato et al. 2005).

Another intriguing locus that has been studied as a possible genetic marker for antidepressant efficacy is the 102 T/C single-nucleotide polymorphism (SNP) in the serotonin$_{2A}$ (5-HT$_{2A}$) gene (*5HTR2A*). A second study, using the same patient sample and the same outcome measures as those of G. M. Murphy et al. (2004), was used to evaluate the role of the 102 T/C SNP in medication intolerance. Survival analysis showed a more or less linear relationship between the number of C alleles and the odds of patients discontinuing paroxetine therapy due to untoward effects (G. M. Murphy et al. 2003). Of note, when these investigators similarly studied the effect of genetic polymorphisms at the hepatic CYP2D6 gene, of which there are 40 known alleles, no signal could be detected with regard to tolerance or efficacy of paroxetine. The authors conclude that pharmacodynamic differences among patients, particularly at the *5HTR2A* site, appear to have a greater impact on paroxetine tolerability than pharmacokinetic variables.

MECHANISM OF ACTION

Despite almost four decades of intensive investigation directed at understanding the pathogenesis and pathophysiology of depression and related psychiatric disorders and the precise mechanism(s) of the therapeutic action of antidepressants, the answers to these questions remain elusive.

Early theorists suggested a causal association between an aberration in synaptic monoamine neurotransmitter concentrations and depression, based largely on the precipitation of depressive

symptoms in a significant number of individuals treated with the antihypertensive agent reserpine, a monoamine-depleting drug (Goodwin and Bunney 1971). The once-celebrated "monoamine hypothesis of depression" provided the theoretical framework for the development and investigation of successive generations of antidepressants. This hypothesis, although seminal, has since been challenged as being too simplistic to explain either the pathophysiological underpinnings of depression or the mechanisms of action of antidepressants (Duman et al. 1997; Ressler and Nemeroff 2000). Antidepressants that effectively increase monoamine neurotransmitter concentrations in the synapse, such as MAOIs, TCAs, SRIs, and SNRIs, clearly implicate the serotonergic and noradrenergic neuronal systems as targets of action of these drugs; however, drug binding to a specific receptor or transporter and consequent manipulation of its affiliated neural circuitry do not necessarily equate to the ultimate mechanism of action of a pharmacological agent (Dubovsky 1994). Although our understanding of antidepressant pharmacology and the biology of depression has grown exponentially, the relationship between the evident pharmacodynamic actions of antidepressants and their well-documented therapeutic effects remains relatively obscure.

Paroxetine and all of the other SRIs cause immediate elevations in extracellular fluid 5-HT concentrations in serotonergic synapses, resulting from the decreased 5-HT clearance associated with 5-HTT inhibition (Wagstaff et al. 2002). Blier et al. (1990) demonstrated that administration of paroxetine initially causes a paradoxical *decrease* in 5-HT neurotransmission, likely caused by activation of a negative feedback system mediated by increased 5-HT binding to the 5-HT_{1A} autoreceptor and subsequent diminution in serotonergic neural activity. After 2 weeks of paroxetine treatment, a desensitization of the 5-HT_{1A} autoreceptors occurs and is associated with an increase in serotonergic neurotransmission (Chaput et al. 1991). The delayed changes in 5-HT_{1A} receptor sensitivity and 5-HT neurotransmission seen after long-term paroxetine administration are temporally associated with clinical improvement, hinting at a possible mechanistic link.

These and related findings led to the study of pindolol, a nonselective β-adrenergic receptor antagonist/5-HT_{1A} antagonist, as a novel approach to accelerate the therapeutic response to SRIs, as well as to convert SRI nonresponders to responders. Preclinical studies revealed greater and more persistent increases in extracellular 5-HT concentrations after treatment with pindolol and an SRI than after treatment with an SRI alone (Dreshfield et al. 1996; Hjorth 1993; Sharp et al. 1997). This observation, coupled with the hypothesis that blockade of the presynaptic 5-HT_{1A} autoreceptor might serve to avert the initial reduction in serotonergic transmission induced by SRI treatment, suggested that the combination of pindolol and paroxetine might produce a more rapid and more robust clinical response (Perez et al. 1999).

Results from open studies supported both hypotheses (Artigas et al. 1994; Blier and Bergeron 1995). Double-blind, placebo-controlled trials also indicated that the addition of pindolol (2.5–5 mg three times a day) to paroxetine in the early phase of treatment for major depression might decrease latency to clinical improvement. However, the augmentation of clinical efficacy with pindolol was not compelling, especially in individuals refractory to monotherapy with paroxetine (Bordet et al. 1998; Perez et al. 1999; Tome et al. 1997; Zanardi et al. 1997). Currently, the available data do not support the use of pindolol to accelerate or augment the efficacy of paroxetine or other SRIs. To be fair, at the doses of pindolol used, PET imaging revealed that only a relatively low percentage of 5-HT_{1A} binding sites were occupied; therefore, the studies should be repeated with adequate doses of pindolol or another 5-HT_{1A} autoreceptor antagonist (Martinez et al. 2000).

Consistent with the potency of paroxetine in blocking NE reuptake are reports that it increases NE concentrations in extracellular fluid, as demonstrated by microdialysis techniques (Hajos-Korcsok et al. 2000). Although not studied extensively, chronic treatment with paroxetine, unlike TCAs such as desipramine, does not produce downregulation of postsynaptic β-adrenergic receptor binding sites in cerebral cortex and hippocampus (Duman et al. 1997).

While 5-HT and β-adrenergic receptor adaptation remains an attractive area of research, attention has increasingly been focused on postreceptor intracellular signal transduction changes observed after long-term antidepressant treatment. Chronic administration of antidepressants has been shown to activate second-messenger systems, such as cyclic adenosine monophosphate (cAMP) and tyrosine kinase B, associated with hippocampal neurons (Duman 1998). Data derived from postmortem human brain tissue studies suggest increased levels of brain-derived neurotrophic factor (BDNF) within the hippocampus of subjects with depression who had been treated with antidepressants, compared with control subjects with depression who had been nonmedicated (Chen et al. 2001). It has been suggested that neuronal injury mediated by stress-related illnesses, such as depression and anxiety, may be reversed by antidepressant-induced increases in BDNF expression in the CNS posited to contribute to clinical response (Duman 1998). Antidepressants from diverse classes, including SRIs, have all been shown to increase the rate of neurogenesis in the hippocampus of adult animals (Duman et al. 2001).

A recent boon to the study of antidepressant effect has been the development and fine-tuning of techniques in the field of functional brain imaging. One study compared the modulation of cortical-limbic systems in depressed patients who were treated with either paroxetine or cognitive-behavioral therapy (CBT) (Mayberg et al. 2004). PET was used to obtain images serially during the course of treatment and revealed interesting distinctions in brain activity in response to the two treatment modalities. Paroxetine responders experienced significant increases in prefrontal cortical activity in the setting of decreases in hippocampal and subgenual cingulate processing. This is in marked contrast to treatment-emergent changes seen in the CBT group in which patients developed increases in hippocampal and dorsal cingulate metabolism subsequent to subtle decreases in dorsal, ventral, and medial frontal cortical processing. The implication is that antidepressant therapy seems to entail a "bottom up" approach distinguishable from the "top down" effect seen with CBT. These results may help explain why combination treatment with antidepressants and various psychotherapies consistently outperforms monotherapy, particularly in moderate to severe depression.

Another major advance in the study of antidepressant action has been the link between paroxetine and the corticotropin-releasing factor (CRF)/hypothalamic-pituitary-adrenal (HPA) axis. It is well established that a sizeable percentage of patients with depression exhibit HPA axis hyperactivity and hypersecretion of CRF from hypothalamic and extrahypothalamic circuits (Heim and Nemeroff 1999). Early life stress, as exemplified by maternal separation, is associated with profound hyperactivity of the HPA axis and increased CRF messenger RNA (mRNA) expression (Nemeroff 1996; Newport et al. 2002). In adult animals, these effects are reversed by chronic, but not acute, paroxetine treatment. Thus, paroxetine exerts multiple effects on neurotransmitter systems implicated in the pathophysiology of mood and anxiety disorders, including 5-HT, NE, and CRF.

Comparison With Other Agents

Tricyclic and tetracyclic antidepressants

The efficacy of paroxetine in major depression has been established in several randomized, placebo-controlled studies, as well as in studies comparing the effects of paroxetine with those of active comparators, including fluoxetine, TCAs, and other agents. The preponderance of early data with paroxetine in establishing efficacy in depression was in comparison trials with TCAs, particularly imipramine and amitriptyline, and placebo. The earliest placebo-controlled trials used 10–50 mg of paroxetine and were 6 weeks in duration. Outcome variables typically used were the Hamilton Rating Scale for Depression (Ham-D), the Montgomery-Åsberg Depression Rating Scale (MADRS), and the

Clinical Global Impressions (CGI) Scale. These trials demonstrated the clear superiority of paroxetine over placebo in the treatment of major depression (Claghorn et al. 1992; Kiev 1992; Rickels et al. 1989; Smith and Glaudin 1992).

A meta-analysis by Montgomery (2001) compared the efficacy and tolerability of paroxetine with those of TCAs, including amitriptyline, imipramine, clomipramine, doxepin, and nortriptyline, and the tetracyclic antidepressants mianserin and maprotiline. Studies included in the meta-analysis were randomized, double-blind, and parallel-group in design; were 6 weeks or less in duration; and employed the Ham-D as the primary outcome measure. Results from the pooled data of 3,758 hospitalized and ambulatory patients from 39 studies showed no overall significant difference in antidepressant response rates between paroxetine and TCAs or tetracyclics, based on a ≥50% reduction in the Ham-D total score or in remission rates, defined as an endpoint Ham-D score of ≤8. Clearly, paroxetine is better tolerated than the TCAs and related heterocyclic antidepressants in terms of lower rates of discontinuation attributed to adverse events. In addition, paroxetine had a greater effect on concomitant anxiety associated with depression, compared with all other studied medications, except clomipramine, which was equally efficacious with regard to anxiolysis.

Despite the overwhelming evidence supporting the equivalent antidepressant efficacy of paroxetine and TCAs, one notable exception exists. The Danish University Antidepressant Group (1990) conducted a multicenter double-blind, placebo-controlled, fixed-dose investigation comparing efficacy and tolerability of paroxetine (30 mg/day) with clomipramine (150 mg/day) and found nonresponder rates to be significantly greater in the paroxetine group. Whereas most of the data supporting the clinical superiority of paroxetine are derived from outpatient studies, the Danish University Antidepressant Group (1990) study comprised only inpatients. These data appear to argue for relative greater efficacy of clomipramine in severe depression; however, two notable confounds exist here. First, higher dosages of paroxetine (e.g., 50–60 mg/day) might well show equivalent efficacy with clomipramine, especially in view of the NET findings described above. Second, Ham-D scores reported in this study were no more severe than those in the outpatient trials, making it difficult to draw any conclusions regarding relative superiority of clomipramine based on severity of depression. All other published studies comparing paroxetine with clomipramine have shown no difference in efficacy in outpatients with depression; paroxetine is, of course, uniformly better tolerated (Guillibert et al. 1989; Pelicier and Schaeffer 1993; Ravindran et al. 1997).

Other SRIs

Because the SRIs, as a class, have become the first-line pharmacological agents in the treatment of depression and a number of anxiety disorders, the results of a large number of studies, mostly sponsored by the pharmaceutical industry, are available. To date, fluoxetine, fluvoxamine, and sertraline have been compared with paroxetine in the treatment of major depression. In addition, given the favorable response of SRIs in several anxiety disorders, clinical trials have compared the clinical ameliorative effects of paroxetine with those of other SRIs on anxiety symptoms associated with depression.

De Wilde et al. (1993) found, at various time points during the trial, statistically significant advantages of paroxetine (20–40 mg/day) over fluoxetine (20–60 mg/day) in total Ham-D score and anxiety subscore. However, by the end of the 6-week study, there was no difference noted in any outcome variable. Geretsegger et al. (1994) studied a group of geriatric patients with severe depression (n = 106) and found a significantly greater proportion of patients treated with paroxetine (20–40 mg/day) than fluoxetine (20–60 mg/day) to have a ≥50% reduction in total Ham-D and MADRS scores by the end of the study; however, no difference was observed in terms of response based on the CGI Scale or between-group differences in MADRS or Ham-D at the termination of the study. Other studies have found paroxetine and fluoxetine to be equally effective in the treatment of major depression and associated anxiety (Chouinard et al. 1999; Fava et al. 1998, 2000; Tignol 1993).

Similar results have been observed in trials comparing paroxetine and sertraline. Zanardi et al. (1996) studied a small group (*n* = 46) of hospitalized patients with psychotic depression and found rates of response to both medications among study completers to be comparable. The intent-to-treat analysis in this trial revealed sertraline (150 mg/day) to be more effective than paroxetine (50 mg/day). The authors suggested that the difference might be attributable to the disproportionately high dropout rate (41%) in the paroxetine group, likely caused by the rapid paroxetine dose titration, compared with the dropout rate in the sertraline group. In the only published study comparing paroxetine and sertraline in a 6-month trial, the two medications had similar antidepressant efficacy and similar ratings on quality-of-life measures (Aberg-Wistedt et al. 2000).

Kiev and Feiger (1997) reported that paroxetine (20–50 mg/day) and fluvoxamine (50–150 mg/day) had equivalent efficacy in the treatment of depression.

Other agents

Paroxetine has also been compared with nefazodone, mirtazapine, bupropion, moclobemide, duloxetine, venlafaxine, and investigational agents such as substance P (neurokinin 1 [NK_1]) antagonists in the treatment of depression. Nefazodone (200–600 mg/day) and paroxetine (20–40 mg/day) were shown to possess similar efficacy and tolerability in an 8-week randomized, double-blind trial of 206 outpatients with moderate to severe depression (Baldwin et al. 1996). In this study, 42.3% of patients in the paroxetine-treated group and 39.7% of patients in the nefazodone-treated group achieved ≥50% reduction in the Ham-D intent-to-treat analysis. Furthermore, both groups had similar significant reductions in associated anxiety. In a study comparing paroxetine (20–40 mg/day) and mirtazapine (15–45 mg/day) in 275 outpatients with major depression, both medications fared equally well in terms of efficacy and tolerability (Benkert et al. 2000). There was evidence of a slightly faster onset of action with mirtazapine, as determined by significant reductions in the 17-item Ham-D and Hamilton Anxiety Scale (Ham-A) scores by week 1 of the study, compared with paroxetine.

A recent randomized open trial was conducted in Italy comparing paroxetine with moclobemide, a reversible MAOI widely prescribed in Europe for the treatment of depression (Pini et al. 2003). The results suggested greater efficacy for paroxetine in the treatment of major depressive disorder with comorbid panic disorder; however, these data are limited by lack of double-blinding.

The SNRI venlafaxine was compared with paroxetine in a population of hospitalized and ambulatory patients with treatment resistance to two or more antidepressants (Poirier and Boyer 1999). Venlafaxine (200–300 mg/day) was superior to paroxetine (30–40 mg/day) in bringing treatment-refractory patients into remission, defined as total Ham-D score of ≤10 at study end (37% vs. 18%, respectively). It should be noted that this definition of remission departs from the customary criterion of Ham-D total score ≤7 and that the study period was rather short (4 weeks), limiting comparison with data from longer-term parallel-group studies with a more standard definition of remission. In the meta-analysis of the venlafaxine worldwide database, in which venlafaxine showed a slight statistically significant advantage in efficacy over SRIs as a class, there was no such difference demonstrated between venlafaxine and paroxetine (Nemeroff et al. 2003). A more recent comparison between venlafaxine XR and paroxetine demonstrated higher rates of remission with venlafaxine in the maintenance treatment of depression (Shelton et al. 2005). An important caveat in interpreting these results is that the doses of paroxetine used never exceeded 20 mg/day and are therefore indicative of only minimal NE reuptake antagonism. Similarly, a study comparing paroxetine with the SNRI duloxetine (40–80 mg/day) revealed higher probability of remission with duloxetine 80 mg/day than with paroxetine (57% and 34%, respectively) (Goldstein et al. 2004). Again, paroxetine was administered to test subjects at the "selective" serotonergic dose of 20 mg/day, too low to exhibit true SNRI activity.

Paroxetine has also been compared with investigational agents such as substance P (NK_1) receptor antagonists. In the Merck-sponsored NK_1 receptor antagonist trials in major depression, paroxetine 20 mg/day was superior to both placebo and the putative novel agent (Cutler et al. 2000).

Depression in the Elderly

Geriatric depression deserves special attention because it is a particularly common, debilitating, and potentially life-threatening disorder (see Weihs et al. 2000). A large number of studies have been conducted with a variety of medications, particularly TCAs and SRIs, in geriatric patients with depression. SRIs are currently the treatment of choice in this population because of their demonstrated efficacy and their relative safety over TCAs and MAOIs. Paroxetine has been shown to be effective in treating individuals with late-life depression in a number of parallel-group trials. Hutchinson et al. (1992) reported that paroxetine (20–30 mg/day) and amitriptyline (50–100 mg/day) were equally effective in a 6-week trial, as determined by similar rates of response and a somewhat faster onset of action for paroxetine. Another study comparing paroxetine (20–30 mg/day) and amitriptyline (50–150 mg/day) yielded similar results, although the time to response was identical between the two agents (Geretsegger et al. 1995). Clomipramine (75 mg/day) and paroxetine (30 mg/day) were equally effective in patients (ages ≥60 years) with depression, as determined by a change in Ham-D and Widlocher Scale scores (Guillibert et al. 1989). Although dropout rates secondary to adverse events were similar, CNS and anticholinergic side effects, not surprisingly, were more frequent in the clomipramine group (41% vs. 18%). Mulsant et al. (1999) reported similar response rates for nortriptyline (mean dosage = 51.4 mg/day) and paroxetine (mean dosage = 23 mg/day) in 80 geriatric patients with depression. The two drug groups had comparable dropout rates.

In view of evidence that elderly patients with depression are more likely to experience earlier relapses than nonelderly depressed patients following successful treatment (Zis et al. 1980), Bump et al. (2001) conducted a study, funded by the National Institute of Mental Health (NIMH), that compared paroxetine (10–40 mg/day) and nortriptyline (20–125 mg/day) in an 18-month, open-label continuation and maintenance trial. No significant differences in rates of relapse (15% for paroxetine and 9.5% for nortriptyline) or time to relapse (60.3 weeks for paroxetine and 58.8 weeks for nortriptyline) were noted. Maintenance efficacy was likewise investigated by Reynolds et al. (2006) using monthly interpersonal psychotherapy (IPT) as a comparator. Patients 70 years or older with major depression who responded to combined treatment with paroxetine and IPT were significantly less likely to have recurrent depression if they received 2 years of maintenance paroxetine compared with placebo. Conversely, maintenance psychotherapy in the absence of drug was ineffective in preventing recurrence. The researchers concluded that the number needed to treat with paroxetine to prevent 1 recurrence was 4 (95% confidence interval [CI] = 2.3–10.9).

In a study by Schöne and Ludwig (1993), paroxetine (20–40 mg/day) was superior in efficacy to fluoxetine (20–60 mg/day) in elderly patients using response rates (≥50% reduction in Ham-D score) as the measure of improvement. Improvements in cognitive function, as measured by the Sandoz Clinical Assessment Geriatric (SCAG) Scale, were similar in both groups at the end of 6 weeks; however, there appeared to be a more rapid response with paroxetine (Gunasekara et al. 1998). A subsequent trial also found paroxetine to be more effective in improving cognitive function at early time points and by study end (Geretsegger et al. 1994). In both studies, paroxetine and fluoxetine were shown to be well tolerated. Weihs et al. (2000) compared paroxetine (10–40 mg/day) and bupropion sustained-release (SR) (100–300 mg/day) in 100 elderly patients with major depression and found similar improvements in all outcomes and comparably low discontinuation rates secondary to adverse events by study end.

One element of concern in treating the frail elderly with paroxetine is the fear of possible anticholinergic side effects. This population is, of course, susceptible to cognitive decline caused by

muscarinic antagonist drugs, which can, in some cases, lead to frank delirium. This concern was formally tested in a study of paroxetine effects on mood and cognition in depressed elderly patients without dementia using fluoxetine as a comparator because of the latter drug's minimal anticholinergic activity (Cassano et al. 2002). The results revealed that paroxetine did not cause cognitive decline but rather produced marked improvement on neuropsychological test scores in depressed elderly patients.

Long-Term Treatment

It is now well recognized that because unipolar depression is often a chronic and recurrent disorder, the prevention of recurrence should be a primary aim. Although there are considerable data supporting the efficacy of paroxetine in short-term trials, only a handful of studies have evaluated its effectiveness in maintaining remission following an acute episode of depression over an extended period.

In a large multicenter open-label trial, Duboff (1993) treated 433 patients with paroxetine (mean dose = 32.9 mg) for 54 weeks. Subjects had moderate to severe depression (mean 17-item Ham-D baseline score = 27.9), and most subjects (81%) had a history of depressive episodes. Approximately two-thirds of the subjects were judged responders (Ham-D score ≤8) at 54 weeks. Nineteen percent of the subjects suffered a relapse (Ham-D score ≥18 at some time point), and 30% withdrew from the study because of adverse events. A 3-year extension study of 110 patients demonstrated the continued antidepressant effects of paroxetine.

Montgomery and Dunbar (1993) studied 172 patients with major depression who had had two or more previous depressive episodes in an 8-week open-label trial with paroxetine (20–40 mg/day), followed by a double-blind, placebo-controlled 1-year extension phase for the acute-treatment responders. The authors reported significantly higher rates of relapse in placebo recipients (43%), compared with paroxetine-treated patients (16%).

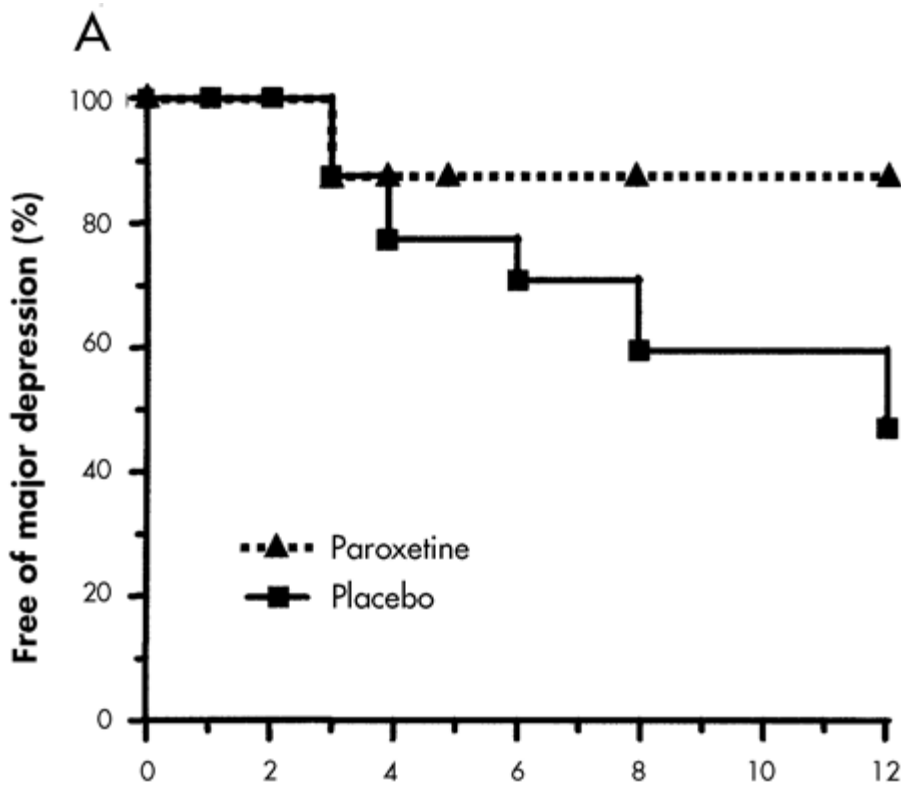
Claghorn and Feighner (1993) compared paroxetine (10–50 mg/day), imipramine (65–275 mg/day), and placebo in 717 patients with major depression. Similar rates of response among all three groups were noted after 1 year, following a blinded 6-week acute course of therapy. However, more placebo-treated patients withdrew from the long-term trial because of lack of efficacy (22%) than did those treated with paroxetine (12%) or imipramine (4%). Moreover, 25% of the placebo group relapsed, compared with 15% of the paroxetine group and 4% of the imipramine group. A substantially greater percentage of patients in the imipramine group (35%) withdrew from the study because of adverse events than in the group receiving paroxetine (15%) or placebo (9%).

In all three studies cited above, the paroxetine doses used in the long-term phases were those typically used in the acute studies (20–40 mg). Thus, for maintenance therapy for depression, the recommended dose of paroxetine is the dose that was effective during the acute phase.

In most patients with an acute major depressive episode, an initial daily dose of 20 mg is usually sufficient for the duration of the illness episode, at least using response as an endpoint (Dunner and Dunbar 1992). However, to improve the likelihood of remission, we recommend increasing the dosage in 10-mg increments per week—up to 50 mg/day or more of the IR form and up to 75 mg/day of the CR form (Nemeroff 1993). Elderly patients and those with renal and hepatic dysfunction should be initiated at a lower dose, with gradual dose titration to therapeutic effect, while monitoring for side effects.

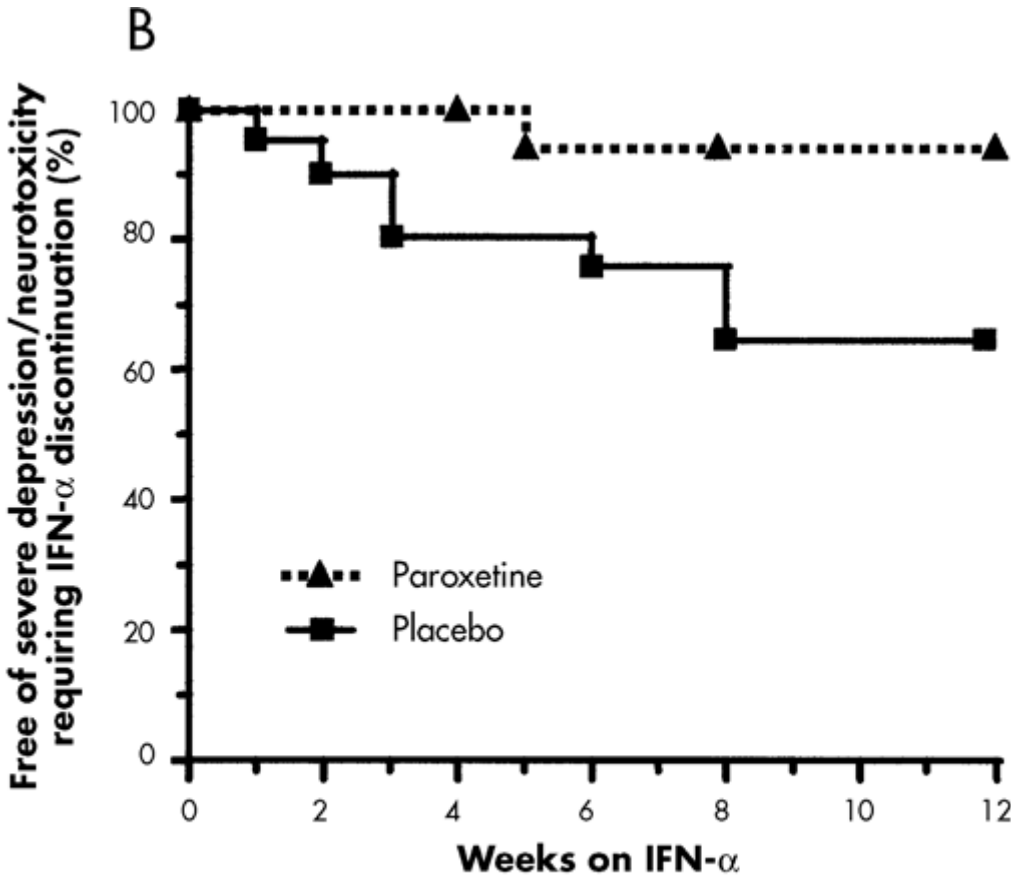
Bipolar Depression

Patients with bipolar disorder present significant clinical challenges, not the least of which are episodes of bipolar depression; nearly 50% of such patients are unresponsive to the antidepressant effects of lithium alone (Sachs 1996). This is a particularly difficult clinical problem because



antidepressants may precipitate manic episodes in patients with bipolar disorder.

Two paroxetine studies have demonstrated the efficacy and safety of this SRI in treating patients with this often treatment-refractory disorder. In one study with lithium-treated patients, Bauer et al. (1999) found paroxetine (20–40 mg/day) to be superior to amitriptyline (75–150 mg/day), on the basis of the Ham-D and CGI–Severity of Illness (CGI-S) scores, although relatively low doses of amitriptyline were used in the 6-week study. In a multicenter double-blind, placebo-controlled comparison trial, Nemeroff et al. (2001) found no difference in response rates among paroxetine (20–50 mg/day), imipramine (150–300 mg/day), and placebo in patients stabilized on a regimen of lithium in a 10-week trial; however, both antidepressants were superior to placebo in treating patients with bipolar disorder with serum lithium concentrations ≤0.8 mEq/L. A study of 27 patients with bipolar I and II disorders receiving a mood stabilizer (lithium or divalproex) at the time of the study evaluated the addition of a second mood stabilizer or paroxetine for the treatment of depression (Young et al. 2000). Both treatment conditions were found to be effective, although patients in the mood stabilizer plus paroxetine group experienced fewer side effects and were more likely to complete the study. Sachs et al. (2007) did not find any difference between paroxetine (10–40 mg/day), bupropion SR (150–375 mg/day), and placebo in a 26-week placebo-controlled study of antidepressant augmentation of mood stabilizer therapy in 366 patients with bipolar depression. Paroxetine was not associated with an increased rate of switch into mania or hypomania in any of these studies.



Depression Associated With Medical Illness

It has been increasingly recognized that depression frequently occurs as a "co-traveler" with a number of medical conditions, and paroxetine has been studied and found to be efficacious in several of these disorders, including rheumatoid arthritis, irritable bowel syndrome, and, most recently, interferon-α-induced depression in malignant melanoma patients (Bird and Broggini 2000; Masand et al. 2001; Musselman et al. 2001). The Musselman et al. (2001) study is a true landmark in the field, because it demonstrated, for the first time, the prevention of an induced depression by pretreatment with paroxetine (Figure 15–3). The association between ischemic heart disease (IHD) and depression has also been extensively studied. Individuals with IHD have a greater risk than the general population for developing depression, and patients with depression are more likely to develop IHD and cerebrovascular disease than are individuals without depression (Anda et al. 1993; Frasure-Smith et al. 1993; J. M. Murphy et al. 1987; Musselman et al. 2007; Simonsick et al. 1995).

Increased platelet reactivity has been observed in individuals with depression, which may explain the increased vulnerability to IHD in this population (Musselman et al. 1996). One study demonstrated normalization of platelet activity in patients with depression, following 6 weeks of treatment with paroxetine 20 mg/day (Musselman et al. 2000). It is unclear whether the antidepressant action of paroxetine or a direct pharmacological effect of the drug on platelet activity resulted in the observed outcome, but the preponderance of evidence with other SRIs supports the latter hypothesis (Serebruany et al. 2003).

Although the physiological association between depression and IHD is still obscure, there is ample evidence that the treatment of depression and comorbid IHD with SRIs is safe and effective and that it reduces the risk of adverse cardiac events (Roose and Spatz 1999). In a landmark study, Roose et al. (1998) reported that paroxetine and nortriptyline were both effective in treating depression in elderly patients with severe heart disease but that paroxetine had a superior safety and tolerability profile. It is currently unknown whether early recognition and treatment of depression will reduce the risk of future cardiac disease.

Childhood and Adolescent Depression

The subject of the role of paroxetine in the treatment of depression in children and adolescents has been one of great controversy and media attention. On June 19, 2003, the FDA released a statement regarding a possible increased risk of suicidal thinking and suicide attempts in children and

adolescents 18 years of age and younger treated with paroxetine for major depressive disorder (U.S. Food and Drug Administration 2003). The statement was based on data from three well-controlled unpublished studies, each showing no benefit for paroxetine above placebo in the treatment of pediatric depression. In addition to the lack of demonstrable efficacy for paroxetine, the data were troubling in that they revealed a two- to threefold increase in suicidal ideation and suicide attempts for paroxetine compared with placebo (3.4% and 1.2%, respectively).

These data contrasted with those of an earlier study supporting the efficacy of paroxetine in the treatment of depression in this population. Keller et al. (2001) conducted a randomized, double-blind study of adolescents (ages 12–18 years) that compared paroxetine with placebo. Paroxetine demonstrated a significant advantage over placebo in most, but not all, outcome variables. It is, however, notable that they reported a rate of suicidal behavior/ideation in the paroxetine group of 5.4%; the rate of the placebo arm was not contained in the report.

More recently, Emslie et al. (2006) reported that paroxetine was no more efficacious than placebo in the treatment of pediatric depression. Using the Children's Depression Rating Scale—Revised, they found that at week 8 of treatment, the total adjusted mean changes in score from baseline for patients receiving paroxetine and placebo were –22.58 and 23.38 points, respectively. In this trial, rates of suicidal ideation and behavior were comparable between the paroxetine (1.92%) and placebo (0.98%) groups. An important distinction between the above-mentioned studies was that Emslie et al. (2006) used lower doses of paroxetine than did Keller et al. (2001); mean dosages were 20.4 and 28 mg/day, respectively. This difference is highly relevant, given that paroxetine has been shown to exhibit marked nonlinear kinetics in children. Findling et al. (1999) showed that an increase in dosage from 10 to 20 mg results in a sixfold increase in child serum paroxetine levels.

The FDA's black box warning concerning antidepressant use and suicidality risk in children and adolescents has already had a major adverse impact on SRI prescribing in the under-18 age group (Nemeroff et al. 2007). For the first time in a decade, an increase in teenage suicide rates has been noted, perhaps due to the decrease in antidepressant prescribing.

Obsessive-Compulsive Disorder

Prior to the introduction of SRIs, the most effective pharmacological treatment for OCD was clomipramine. Early studies showed that patients with both OCD and depressive symptoms fared better on clomipramine than patients treated with other available TCAs (Pigott and Seay 1999). Later work revealed that clomipramine was effective in treating OCD, independent of the presence or severity of comorbid depressive symptoms (Fineberg et al. 1992).

The notable efficacy of clomipramine in OCD was attributed to its remarkable potency as a 5-HT reuptake inhibitor (Benfield et al. 1980). The 5-HTT-specific action of clomipramine, coupled with its specificity in targeting obsessive-compulsive symptoms, led to the formulation of the "serotonin hypothesis of OCD," which posited disturbed 5-HT neurotransmission in OCD (see D. L. Murphy et al. 1989; Zohar and Insel 1987). Consequently, researchers focused their efforts on identifying and developing other agents that were effective in treating OCD, without the unfavorable side effects of TCAs, including their anticholinergic, antihistaminergic, and antiadrenergic properties.

Currently, among the SRIs, fluvoxamine, fluoxetine, sertraline, citalopram, and paroxetine have been shown to be effective, in comparisons with placebo, in the treatment of OCD in randomized, double-blind trials (Greist et al. 1995; Montgomery et al. 2001). Although two meta-analyses assessing the efficacy and tolerability of clomipramine and SRIs in OCD seemed to favor clomipramine in terms of overall effectiveness (Greist et al. 1995; Piccinelli et al. 1995), the only placebo-controlled multicenter study to compare clomipramine (50–250 mg/day) directly with an SRI, paroxetine (20–60 mg/day), revealed equal efficacy (Zohar and Judge 1996). Moreover, significantly more patients receiving clomipramine dropped out of the study because of side effects compared with patients

receiving either paroxetine or placebo. These results suggest that paroxetine is a safe and effective treatment for OCD and is preferable to clomipramine as a first-line agent.

More recent work in the field of functional brain imaging has elucidated paroxetine's effect on neural processing in patients suffering from OCD. Saxena et al. (2002) demonstrated that paroxetine treatment led to significant decreases in metabolic activity in the right caudate, bilateral orbitofrontal thalamus, and bilateral striatum. This group later published a study (Saxena et al. 2003) indicating that pretreatment hyperintensities in the right caudate were the imaging findings most predictive of response to paroxetine. Such findings, which implicate striatal far more than limbic structures, have lent credence to speculation that OCD is more nosologically similar to tic disorders such as Tourette's syndrome than to anxiety disorders (Grados et al. 2001).

In addition to paroxetine's proven efficacy in adult OCD, the drug has also been shown to be of benefit in pediatric OCD. A randomized multicenter, double-blind, placebo-controlled trial revealed paroxetine to be an effective and generally well-tolerated treatment for OCD in children and adolescents (Geller et al. 2004). Patients with comorbid major depressive disorder were excluded from the study, and the authors reported only one incident of treatment-emergent suicidal behavior or ideation. However, because the onset of suicidality in this case occurred 4 days after the patient was asked to leave his guardian's house and forced to move into a youth shelter, the incident was surmised to be situational rather than an untoward response to paroxetine.

In adults, daily doses of ≥60 mg of paroxetine are usually required to optimally treat OCD. Although patients characteristically respond to treatment within 3–4 weeks, clinical improvement may not be discernible until 10–12 weeks; therefore, a standard drug trial of up to 12 weeks should be conducted before an alternative medication is considered (Rasmussen et al. 1993). Why patients with OCD require higher mean doses of paroxetine than patients with unipolar depression is unclear.

Panic Disorder

Estimates from the National Comorbidity Study indicate that the lifetime prevalence rate of panic disorder in the general population is approximately 3.5% (Kessler et al. 1994). Nearly 30% of patients with panic disorder have comorbid depression, and 15% of patients with panic disorder display substance or alcohol abuse. Considerable evidence suggests that patients with panic disorder who have comorbid depression have higher suicide attempt rates than patients with major depression alone (Weissman et al. 1989). These statistics underscore the serious morbidity and mortality of this condition and the need for effective treatment.

Paroxetine was the first SRI granted FDA approval for the treatment of panic disorder. In a 12-week trial of patients with panic disorder that compared paroxetine (20–60 mg/day) and clomipramine (50–150 mg/day) with placebo, Lecrubier et al. (1997) reported that paroxetine was as efficacious as clomipramine in all efficacy measures. Indeed, paroxetine showed significant improvements in the mean change in full panic attacks and in the proportion of subjects who became panic free. In addition, a faster onset of action was noted with paroxetine. Study completers were offered the opportunity to continue in their respective treatment arms for an additional 9 months (Lecrubier and Judge 1997). The results demonstrated the enduring efficacy of both medications; however, 19% of clomipramine-treated patients dropped out, because of adverse events, compared with 7.4% for the paroxetine-treated patients and 6.7% of the subjects receiving placebo. Paroxetine is clearly as effective as clomipramine in the treatment of panic disorder, and it is better tolerated.

The psychotherapeutic treatment of panic disorder has been studied extensively, and evidence for the effectiveness of CBT in this disorder is considerable. Direct comparison of paroxetine (20–60 mg/day) with CBT, clomipramine (50–150 mg/day), and placebo, in a study involving 131 patients, revealed paroxetine to be more effective than both CBT and placebo in all outcomes, except for panic frequency (Bakker et al. 1999). Surprisingly, patients treated with CBT alone in this study fared no differently

than patients given placebo. The authors suggested that the apparent lack of effect of CBT as monotherapy, a finding that contrasts with results from previous studies supporting its efficacy, was due to the inclusion in the study of an unusually high proportion of severely agoraphobic individuals. Thus, patients with more severe pathology may require initial treatment with paroxetine (or possibly another SRI) before CBT is employed in order to diminish anxiety to a degree that renders psychotherapy more tolerable; however, these data should be replicated before conclusions are drawn. In a study comparing paroxetine (20–60 mg/day) with placebo in patients receiving concomitant CBT for panic disorder, paroxetine was better at reducing both the total number of panic attacks by ≥50% from baseline and the number of panic attacks to one or zero by the end of the 12-week study (Oehrberg et al. 1995). Therefore, the combination of CBT and paroxetine is more effective in the treatment of panic disorder than CBT alone.

In general, patients with panic disorder should initially be treated with a low dose of paroxetine (e.g., 10 mg/day), with gradual increases in dose, as clinically indicated. The data that led to FDA approval indicated that 40 mg/day is the minimum effective dosage for this condition; however, clinical experience indicates that lower dosages may be sufficient in some patients and higher dosages may be required in other patients (Ballenger et al. 1998). The standard duration of treatment ranges from 6 to 12 months; however, rates of relapse appear to be greater than those for major depressive disorder, indicating that panic disorder may require an indefinite course of treatment (Hirschfeld 1996).

Social Anxiety Disorder

Paroxetine, sertraline, fluvoxamine CR, and venlafaxine XR are the only medications with FDA approval for the treatment of social anxiety disorder, which is also known as social phobia. The efficacy of paroxetine in the treatment of social anxiety disorder was first suggested by the results of open clinical trials conducted in the mid-1990s (Mancini and van Amerigen 1996; M. B. Stein et al. 1996). These studies were initiated following the appearance of several case reports, as well as open- and placebo-controlled trials involving other SRIs, that documented the effectiveness of this class of drugs in treating social anxiety disorder (Czepowicz et al.1995; Katzelnick and Kobak 1995; van Amerigen et al. 1993; van Vliet et al. 1994).

Shortly thereafter, a number of double-blind, placebo-controlled paroxetine studies were conducted that supported these early positive findings (Baldwin 2000; Lydiard and Bobes 2000; M. B. Stein et al. 1998). In the first such trial, 187 patients with social anxiety disorder were randomized to treatment with a flexible-dosing regimen of paroxetine (20–50 mg/day) or placebo (M. B. Stein et al. 1998). Fifty-five percent of patients in the paroxetine group, versus 24% of patients in the placebo group, were assessed as either "much improved" or "very much improved" on the CGI–Improvement (CGI-I) scale by the end of the 12-week study. Improvement in the primary outcome measures in the paroxetine group, compared with the placebo group, was significant as early as 2 weeks after initiation of the treatment. These findings were confirmed in a second large placebo-controlled multicenter trial that reported significant improvements in primary efficacy variables by week 4 (Baldwin et al. 1999). Lydiard and Bobes (2000) reported that the optimal daily dose of paroxetine for the treatment of social anxiety disorder is 20–40 mg, adding that there is no additional efficacy observed at a dose of 60 mg. Because nearly 80% of social anxiety disorder patients have comorbid depressive or anxiety disorders, such individuals were excluded from the three studies described above to ensure that the treatment response observed was specific for social phobia (Baldwin 2000).

To date, there are no published data comparing paroxetine with other SRIs, benzodiazepines, or MAOIs; however, there is a head-to-head comparison with venlafaxine XR in the treatment of social anxiety disorder. Liebowitz et al. (2005) found that response rates were similar between the paroxetine and venlafaxine XR samples (62.5% and 58.6%, respectively) and that both agents were superior to placebo (36.1% response rate). D. J. Stein et al. (2002) evaluated whether paroxetine's

efficacy in social anxiety disorder could be maintained after treatment discontinuation. A single-blind acute-treatment phase (12 weeks) was used to identify paroxetine responders, who then continued into the maintenance phase, with 162 receiving paroxetine and 161 receiving placebo. Both groups were followed for 24 weeks. At the end of the study, significantly fewer patients relapsed in the paroxetine arm than in the placebo arm (14% vs. 39%). These data indicate that long-term maintenance treatment of social anxiety disorder may be necessary, although more research is needed in this disorder to guide clinical decision making.

In a double-blind, randomized study of children and adolescents (ages 8–17 years) with social anxiety disorder, paroxetine (10–50 mg/day) was found to be superior to placebo on the basis of the number of treatment responders who had a CGI-I score of 1 (very much improved) or 2 (much improved) at the end of 16 weeks (Wagner et al. 2004). In the intent-to-treat population (n = 319), treatment responders were seven times more likely to have received paroxetine than placebo. It is important to note that a total of 5 patients in the paroxetine group, versus none in the placebo group, exhibited suicidal threats or gestures. The authors noted that none of these 5 cases was considered serious, none involved clear evidence of a suicide attempt, and none was attributed to the study medication by the investigator.

Generalized Anxiety Disorder

GAD is characterized by persistent and uncontrollable worry associated with somatic and psychic symptoms of anxiety, such as muscle tension, difficulty concentrating, and sleep disturbance. GAD is a relatively common disorder, with a lifetime prevalence rate of around 3% in the general population (Judd et al. 1998). Although the classification of this disorder has undergone considerable revision since its introduction in DSM-III (American Psychiatric Association 1980), its negative impact on quality of life and high medical resource utilization are well documented (Roy-Byrne 1996; Wittchen et al. 1994). Currently, a number of treatments for GAD are available; however, concerns over dependence and abuse potential with benzodiazepines, efficacy of and patient satisfaction with buspirone, and the side effects associated with the TCAs have led to a growing interest in the development and investigation of newer agents (see Pollack et al. 2001). Extended-release venlafaxine, escitalopram, duloxetine, and paroxetine have all been approved by the FDA for the treatment of GAD.

It has been estimated that nearly 70% of GAD patients have comorbid depression (Judd et al. 1998). To assess the specificity of paroxetine in the treatment of GAD, investigators have excluded subjects with depression and other Axis I disorders. The first such published study supporting the use of paroxetine in GAD compared it with both imipramine and 2'-chlorodesmethyldiazepam, a benzodiazepine (Rocca et al. 1997). Not surprisingly, patients receiving the benzodiazepine showed the earliest improvement in symptoms, based on reduction in Ham-A total scores; however, both paroxetine and imipramine showed significant reductions in Ham-A total score, exceeding that of 2'-chlorodesmethyldiazepam by week 4 of the 8-week trial. Pollack et al. (2001) studied 326 nondepressed subjects who had moderate to severe GAD in an 8-week placebo-controlled study. Paroxetine produced a significant improvement in the Ham-A score, compared with placebo, as well as significant improvements in social impairment, as measured by the Sheehan Disability Scale (SDS). These results were replicated by a group that demonstrated SDS-measured response rates of 62% and 68%, respectively, with daily paroxetine doses of 20 mg and 40 mg, compared with a 46% response rate with placebo (Rickels et al. 2003). Because paroxetine is effective in the treatment of major depression and several anxiety disorders, it should be effective in patients with comorbid GAD and depression; however, no such clinical trials have been conducted.

Like other anxiety disorders, GAD is a chronic condition with a characteristic relapsing and remitting natural course. Long-term treatment of GAD with paroxetine (20–50 mg/day) was studied in a randomized, placebo-controlled trial (Stocchi et al. 2003). Following an 8-week single-blind treatment

phase involving 652 moderately to extremely ill patients (CGI-S score = 4–7), 566 treatment responders were randomized in a double-blind fashion to paroxetine (20–50 mg/day) or placebo for 24 weeks. At the end of the study, 39.9% of the placebo-treated patients had experienced a relapse, compared with only 10.9% of the paroxetine-treated patients. These findings demonstrate that the efficacy of paroxetine in the treatment of GAD persists for up to 6 months. Even longer-term data are needed to assess the continued efficacy of paroxetine beyond this time period.

Head-to-head comparisons between paroxetine and other medications in the treatment of GAD are sparse. One such study compared paroxetine 20–50 mg/day with escitalopram 10–20 mg/day (Bielski et al. 2005). Although there was no significant difference in efficacy between the two medications, as measured by the Ham-A, the authors noted considerably higher rates of adverse events, leading to withdrawal from the trial, in patients treated with paroxetine compared with those treated with escitalopram (22.6% vs. 6.6%). Treatment-emergent side effects recorded more frequently with paroxetine therapy included insomnia, constipation, ejaculation disorder, anorgasmia, and decreased libido. Conversely, diarrhea and upper respiratory tract infection were more common with escitalopram than with paroxetine. One possible explanation for the divergence in dropout rates may be the seeming disparity in dose ranges between the two medications. Paroxetine was titrated to high-normal doses (between 30 and 50 mg/day) in 63% of subjects, whereas escitalopram was raised only to a dose representing its high-normal range (20 mg/day) in 54% of subjects and never above that. It is important to note that specific adverse events were not stratified by medication dose in the published results.

Given the high prevalence rate and morbidity associated with GAD, the addition of paroxetine to the armamentarium of effective pharmacological agents for this disorder represents a significant clinical advance. In addition to improvement in the disabling symptoms of anxiety and coexistent depression, patients can expect to achieve an improved quality of life. In summary, paroxetine is an effective and well-tolerated treatment choice for patients with GAD. Clinical experience and investigative research indicate that the usual effective dosage for treating GAD is 20 mg/day (Paxil 2001).

Posttraumatic Stress Disorder

The lifetime prevalence of PTSD, an illness causing marked impairment in individual daily functioning and a considerable burden to society as a whole, has been estimated to be as high as 10.5% for women and 5% for men. In addition, PTSD tends to be a chronic disabling condition with an 80% comorbidity rate with other psychiatric disorders (Kessler et al. 1995).

As a class, the SRIs are the most studied medications for this disorder. Fluoxetine, sertraline, and paroxetine have all been shown to be effective in treating PTSD in placebo-controlled trials (Brady et al. 2000; van der Kolk et al. 1994). Paroxetine, with its established efficacy in a wide range of mood and anxiety disorders, has been studied in considerable detail in PTSD. Indeed, paroxetine first fared well in a small open-label trial of patients with chronic (greater than 3 months' duration), non-combat-related PTSD (Marshall et al. 1998). In a subsequent study, Marshall et al. (2001) conducted a large randomized, placebo-controlled trial in patients with chronic PTSD (*n* = 551 intent-to-treat group). The authors found significant improvements in all efficacy measures in paroxetine-treated (20 mg/day and 40 mg/day) patients, compared with placebo-treated patients. Paroxetine was effective in treating the three main cluster groups of reexperiencing, avoidance/numbing, and hyperarousal, with significant separation from placebo at all measured time points, beginning at week 4. In addition, there were significant reductions in disability and depression, compared with placebo, in both paroxetine treatment groups. Patients with comorbid major depression (40%) responded just as favorably as subjects without depression. Tucker et al. (2001) demonstrated, in a 12-week double-blind trial, that 20–50 mg of paroxetine was superior to placebo in the intent-to-treat population (*n* = 307), as assessed by improvement on the Clinician-Administered PTSD Scale—Part 2 (CAPS-2) and on all secondary measures by week 4. Male and female subjects responded equally well

to paroxetine. Tucker's group went on to show, in an open-label trial, that paroxetine treatment led not only to improvement in subjective symptoms but also to normalization of elevated heart rate and blood pressure reactivity in PTSD patients with comorbid depression (Tucker et al. 2004). Additionally, Bremner et al. (2003) reported that yearlong treatment of PTSD patients with paroxetine (10–50 mg/day) was associated with significant improvements in verbal declarative memory, along with increases in hippocampal volume. These findings, when taken together, suggest that paroxetine (20–50 mg/day) is an effective treatment for chronic PTSD.

Long-term studies are important to assess the efficacy of paroxetine during maintenance treatment. Furthermore, the potential synergy of the combination of paroxetine and psychotherapy for optimal treatment response in PTSD has emerged as an area of interest for clinical investigators.

Premenstrual Dysphoric Disorder

Premenstrual syndrome and the more severe PMDD together affect up to 8% of women of reproductive age and are characterized by disabling psychological and physical symptoms (Steiner and Pearlstein 2000). Features of both conditions typically include bloating, weight gain, breast tenderness, poor concentration, and disturbed sleep and appetite, which manifest in the luteal phase of ovulation and disappear upon menstruation. These symptoms are cyclical, predictably appearing prior to each menses (Dimmock et al. 2000).

The psychological symptoms of PMDD are more severe and prominent and include irritability, dysphoria, tension, and mood lability. The pathophysiology of PMDD remains obscure; however, it may involve altered sensitivity to circulating ovarian hormones. There is also ample evidence that alterations of serotonergic systems play an important role in the production of these premenstrual symptoms, partly because serotonergic agents such as SRIs and clomipramine are effective in the treatment of these disorders but noradrenergic antidepressants are not (Steiner and Pearlstein 2000).

The classification of PMDD as a biologically determined disorder is partly grounded both on twin studies, suggesting a strong genetic component, and on the elimination of symptoms with surgical or medical suppression of ovarian hormonal activity (Condon 1993). Although conservative treatment, such as diet restrictions and exercise, may be somewhat helpful, women with PMDD often do not respond adequately to these nonpharmacological measures and require medication for remission of symptoms (Steiner and Born 2000).

The benefit of paroxetine in PMDD has been shown in a number of clinical studies. It was shown to be significantly more effective than maprotiline, an NE reuptake inhibitor, in reducing both psychological and somatic symptoms of PMDD in a double-blind, placebo-controlled study of 65 women (Eriksson et al. 1995). Two smaller open trials revealed positive findings with paroxetine treatment (Sunblad et al. 1997; Yonkers et al. 1996). A more recent double-blind, placebo-controlled study demonstrated that paroxetine CR (25 mg/day) was both well tolerated and effective in the treatment of PMDD (Cohen et al. 2004). Steiner et al. (2005) further clarified that the disorder could be successfully managed with paroxetine CR by using an intermittent luteal phase dosing schedule. Patients were instructed to begin drug therapy 14 days prior to their estimated time of next menses and to continue only until the onset of menstruation. They then stayed off the medication during the intervening follicular phases of their cycle. The patients in the paroxetine CR arm did significantly better than those in the placebo group; however, this intermittent-dosing regimen was not tested against standard fixed-dosing schedules. It is likewise unknown whether such "drug holidays" lead to better adherence or outcomes.

Menopausal Vasomotor Symptoms

In addition to its proven efficacy in PMDD, paroxetine (20 mg/day) was shown to be effective in the treatment of postmenopausal hot flashes in breast cancer survivors with chemotherapy-induced ovarian failure in two open trials (Stearns et al. 2000; Weitzner et al. 2002); for a review, see

Bordeleau et al. 2007) and in a double-blind study (Stearns et al. 2005). Paroxetine CR (25 mg/day) was subsequently found to be efficacious in treating perimenopausal hot flashes in a placebo-controlled trial (Stearns et al. 2003). The drug's usefulness in this setting is underscored by recent concerns about the safety of hormone replacement therapy (HRT), hitherto the treatment of choice (H. D. Nelson et al. 2002). For clinicians and patients concerned about the long-term consequences of estrogen replacement in treating hot flashes, paroxetine provides a reasonable alternative.

SIDE EFFECTS AND TOXICOLOGY

The popularity of SRIs, as a class, in the treatment of psychiatric disorders is owed not to their superiority in efficacy over their predecessors but rather to their overall tolerability and safety. In general, SRIs share a common profile in terms of severity and frequency of side effects. The side-effect profile of paroxetine has been studied extensively in comparison studies with other psychotropic medications and placebo. The most commonly cited adverse experiences in patients treated with paroxetine are, in order of frequency, nausea, headache, somnolence, dry mouth, asthenia, sweating, constipation, dizziness, and tremor (Boyer and Blumhardt 1992).

According to the worldwide preregistration clinical trial database, anticholinergic side effects, tremor, dizziness, postural hypotension, and somnolence were more common in comparison drugs—generally TCAs—in mostly short-term studies (Jenner 1992). Nausea and abnormal ejaculation were more frequently reported with paroxetine than with active controls. In these early trials, a greater proportion of patients in the antidepressant comparison and placebo groups withdrew because of adverse events than did patients in the paroxetine group. According to preregistration data, 13% of patients taking paroxetine dropped out prior to study's end because of side effects, compared with 19% for other agents and 5% for placebo. The most common side effect associated with early termination for paroxetine was nausea. Clinical experience demonstrates that this significant complaint can be mitigated with a conservative starting dose and administration with food, as well as with the use of the CR form of the compound. Furthermore, patients reported that nausea diminishes markedly with prolonged administration, a phenomenon also noted in long-term trials (Jenner 1992).

According to the limited data available comparing paroxetine directly with other newer-generation antidepressants, notably venlafaxine, sertraline, and fluoxetine, tolerability was similar and early termination rates were also comparable (Aberg-Wistedt et al. 2000; Ballus et al. 2000; Poirier and Boyer 1999; Schöne and Ludwig 1993; Tignol 1993). A possible exception to this might be mirtazapine. As described earlier in this chapter (see "Pharmacogenomics" section), the presence of the S allele in the 5-HTT gene and the C allele in the 5-HT_{2A} receptor gene both confer lower tolerability and earlier discontinuation in patients taking paroxetine. Neither of these polymorphisms had any effect on tolerability of mirtazapine, which demonstrated lower rates of adverse events and discontinuation in comparison with paroxetine (G. M. Murphy et al. 2003, 2004). As noted earlier, elderly patients do not appear to be more susceptible to the side effects of paroxetine, and cognitive function remains intact or improves during treatment (Cassano et al. 2002; Nebes et al. 1999).

The paroxetine CR formulation has been compared with paroxetine IR in a placebo-controlled, randomized trial (Golden et al. 2002). Although the frequency of reported side effects was similar between the two active agents, paroxetine CR was significantly less likely to induce nausea (14%), compared with paroxetine IR (23%), in the first week of treatment. A later comparison that used time to discontinuation and economic costs as primary outcome measures found that patients on the CR formulation remained on therapy longer, resulting in better outcomes and lower health care costs (Sheehan et al. 2004). Because nausea is the most frequently reported side effect associated with paroxetine treatment and because it often results in medication discontinuation, paroxetine CR may offer a clinical advantage over the IR formulation in terms of improved treatment compliance and overall clinical effectiveness.

Sexual Side Effects

Sexual dysfunction is a liability associated with many psychotropic medications, and the full scope of this problem is only recently gaining its deserved recognition. When assessing emergence of side effects, most clinical studies rely on spontaneous reporting of adverse experiences. Because most patients do not feel comfortable reporting sexual side effects, it is not surprising that treatment-emergent sexual dysfunction is often underreported in these trials. In one prospective study, specific inquiry about sexual dysfunction with treatment of fluoxetine, paroxetine, sertraline, or fluvoxamine resulted in nearly a threefold increase in reporting of sexual problems, compared with only spontaneous communication (Montejo-Gonzalez et al. 1997).

Typically, data derived from clinical studies estimate sexual disability attributed to SRIs to be less than 20%, whereas in clinical practice the incidence appears to be significantly higher, perhaps as high as 40%. This side effect clearly has an adverse effect on medication adherence, partly because discussion of sexual issues is difficult for patients and clinicians alike. Although all SRIs and venlafaxine have been associated with male and female sexual dysfunction, there is a prevailing view among clinicians that this side effect might be more problematic with paroxetine, although few controlled data are available to address this issue. In a comparison study of 200 subjects treated with paroxetine, fluoxetine, fluvoxamine, or sertraline, paroxetine treatment was associated with higher rates of anorgasmia or difficulty with ejaculation and impotence in both men and women (Montejo-Gonzalez et al. 1997). Significant differences among the four drugs were not noted with respect to decrease in libido, delay in orgasm, or patient attitude toward treatment-induced sexual disability. In a large cross-sectional observational study (*N* = 6,297) conducted by Clayton et al. (2002), paroxetine was associated with the highest prevalence of overall sexual dysfunction, compared with a wide range of novel antidepressants, including mirtazapine, venlafaxine, sertraline, citalopram, fluoxetine, nefazodone, and bupropion. However, a significant difference between paroxetine and the other agents was observed with only fluoxetine, bupropion, and nefazodone. Waldinger et al. (1998) studied 51 men without depression who had premature ejaculation and noted greater delay in time to ejaculation during paroxetine treatment, compared with treatment with fluoxetine, fluvoxamine, and sertraline.

The above findings have led to the use of paroxetine and other SRIs in the treatment of premature ejaculation (PE) in men (Balon 1996). Head-to-head comparisons between paroxetine and other antidepressants in the treatment of PE currently exist only for dapoxetine and mirtazapine. Safarinejad (2006) used a measure called the Intravaginal Ejaculatory Latency Time (IELT) to test paroxetine's effectiveness in slowing down male climax versus dapoxetine, a short-acting SRI that is currently awaiting FDA approval for the treatment of PE. Male patients taking paroxetine in a randomized, double-blind fashion showed IELT increases from a mean of 31 seconds at baseline to 370 seconds with treatment, whereas subjects taking dapoxetine (38 seconds to 179 seconds) or placebo (34 seconds to 55 seconds) did not fare as well. Ejaculatory latency was likewise compared, using the IELT measure, between paroxetine and mirtazapine. In a 6-week double-blind study, treatment with paroxetine (20 mg/day), but not mirtazapine (30 mg/day), resulted in significant delays in orgasm and ejaculation in men with PE (Waldinger et al. 2003).

Sexual side effects emerge in a dose-dependent fashion and do not appear to diminish with prolonged administration. Strategies to lessen the impact of psychotropic medications on sexual function include using dosage reduction, changing to a different antidepressant with lesser sexual side-effect liability, and adding an agent, such as sildenafil, yohimbine, buspirone, cyproheptadine, amantadine, methylphenidate, or bupropion, to reverse the sexual side effects (Rosen et al. 1999). Controlled studies demonstrating the efficacy of these agents are largely lacking, with one exception. Ephedrine, an α- and β-adrenergic agonist previously shown to enhance genital blood flow in women, was evaluated in 19 women experiencing SRI-induced sexual dysfunction from paroxetine, sertraline, or fluoxetine (Meston 2004). Although ephedrine (50 mg taken within 1 hour of sexual activity onset)

significantly improved self-reported scores of desire and orgasm intensity compared with baseline, these measures, in addition to sexual arousal and satisfaction, were also similarly enhanced by placebo.

Suicidality

Apprehension surrounding the alleged relationship between SRIs and suicide first gained media attention in the late 1980s, largely due to incidental reports of supposed SRI-induced suicide and homicide circulated in the lay press. The issue once again gained international attention in October 2004, when the FDA ordered drug companies to place a black box warning on all antidepressants, stating that suicidal behavior might increase in children and adolescents taking these drugs. The FDA based this decision on a pooled analysis of 24 antidepressant trials involving more than 4,400 children and adolescents. Paroxetine was not singled out in this analysis, and, indeed, the warning applies to all antidepressants. Data on paroxetine and suicidal behavior in pediatric depression are covered more specifically in the "Childhood and Adolescent Depression" subsection earlier in this chapter.

Concerns about a link between antidepressant usage and suicidal ideation led FDA regulators to request that antidepressant manufacturers examine their databases for a similar link in adult patients. GlaxoSmithKline (Paxil/Seroxat) responded by supporting a meta-analysis of its clinical data comparing suicidality between paroxetine and placebo. The researchers found that 0.32% (11 of 3,455) of people taking paroxetine for depression attempted suicide, compared with 0.05% (1 of 1,978) of depressed patients taking placebo, an odds ratio of 6.7 (see GlaxoSmithKline 2006). Incidences of completed suicide in both samples were exceedingly rare, with one reported in the paroxetine sample versus none reported with placebo. Such data need to be considered cautiously for several reasons. First, it should be noted that neither suicidal ideation nor self-harming behaviors were among the main outcome measures in any of the pooled studies. Procedures to assess suicidality are not standardized and are based largely on unsolicited and unstructured reports and observations. Second, transient suicidal thinking must be viewed in the context of the overall risk–benefit analysis of paroxetine in the treatment of adults with major depressive disorder, an illness for which there is robust evidence supporting its efficacy.

In late 2006, an FDA advisory panel used the above data, along with findings from a total of 372 randomized, placebo-controlled antidepressant trials (involving close to 100,000 adult patients), in their decision to recommend that the black box warning be extended to cover young adults up to their mid-20s (U.S. Food and Drug Administration 2007). They reported that in patients 18–24 years of age, antidepressant use was associated with four cases of suicidal ideation per 1,000 patients treated, whereas drug therapy for patients older than 30 years was unequivocally protective against suicidality. The decision to extend the warning was made despite evidence that the initial warning might have had dangerous, unintended consequences for children and adolescents suffering from depression in the United States. Nemeroff et al. (2007) analyzed prescription data and physician surveys detailing prescription practices to identify trends in antidepressant use among children and adolescents. They found that from April 2002 to February 2004, antidepressant prescriptions among children and teens increased by an average of 0.79% a month. Between February 2004 and July 2004, prescriptions declined by an average of 4% a month. The latter period corresponds with the time that the initial FDA advisory committee was holding highly publicized hearings regarding a link between antidepressant treatment and suicide attempts in depressed children. The Centers for Disease Control and Prevention (2007) recently reported that suicide rates in American children and adolescents increased by a staggering 18% in 2004 after 10 straight years of steady decline.

Suicide and attempted suicide were the main outcome measures in a recently published highly powered cohort study in which 15,390 patients, representing all subjects hospitalized in Finland for a confirmed suicide attempt between January 1997 and December 2003, were followed prospectively to ascertain whether active antidepressant treatment was associated with change in risk compared with

patients taking no medication (Tiihonen et al. 2006). The investigators concluded that current SRI treatment across age groups was associated with a substantial decrease in overall mortality (relative risk of 0.59). Paroxetine was noted to confer increased risk of death in the population of patients between the ages of 10 and 19 years (relative risk: 5.44) compared with subjects who were not taking an antidepressant during the follow-up period. This was a naturalistic study, and it should be emphasized that patients are most likely to opt for antidepressant treatment when they are most depressed and that severe depression is a risk factor for suicide attempts. Still, it should also be noted that patients 10–19 years of age had higher risks of suicidal ideation with paroxetine than with other SRIs studied in the trial.

Theories attempting to explain the possible association between antidepressants and the onset of suicidality have been a part of psychiatric folklore since these medicines became available decades ago. Paroxetine in particular has several characteristics that may explain its implication in suicidal adverse events in children and adolescents with major depressive disorder. As previously noted, it has nonlinear kinetics, such that small dosage increases produce dramatic increases in child serum levels. Such high levels could lead to activation, akathisia, or disinhibition, any of which might explain suicidal thoughts or acts (Brent 2004). This effect is even more dramatic in those children who are slow metabolizers of the CYP2D6 isoenzyme (roughly 10% of the Caucasian population) (Riddle 2004). Additionally, paroxetine has a relatively short half-life (11 hours vs. 5 days with fluoxetine), and limited dosing adherence, not uncommon in children and teens, could lead to SRI discontinuation syndrome and dysphoria (Brent 2004). Another possibility is that paroxetine, along with venlafaxine and other NE-acting antidepressants that have similar links to suicidal risk in depressed children, might lead to manic or mixed-episode switching in children or adolescents who have undiagnosed bipolar disorder (Rihmer and Akiskal 2006). These possibilities require further study to elucidate.

Regardless of whether the association between antidepressants and transient suicidal activation in young people is causal, clinicians should inform their patients about the possible risks and should monitor depressed patients closely once paroxetine or any other antidepressants are prescribed, particularly during the early phase of treatment. The FDA advisory committee has made it clear that the black box warning should not dissuade physicians from prescribing antidepressants to patients in need (U.S. Food and Drug Administration 2007).

Medical Safety

Paroxetine treatment in clinical trials has not been associated with any significant abnormalities in standard laboratory tests, including hematological indices and chemistry panels, electroencephalogram (EEG), or electrocardiogram (ECG). One possible concern regarding paroxetine had been the potential for decreased heart rate variability (HRV), because depressed patients have been shown to exhibit lower HRV than nondepressed persons and this decrease represents a significant risk factor for myocardial infarction (Gorman and Sloan 2000). Moreover, NE reuptake–inhibiting antidepressant drugs have been shown to cause further decreases in this electrophysiological variable (Rechlin 1994). Decreases in HRV have been implicated in increased cardiovascular mortality (Carney et al. 2005), and depression itself has been conclusively shown to be a risk factor in the development of heart disease (Musselman et al. 1998). Davidson et al. (2005) demonstrated that paroxetine (doses up to 40 mg/day) resulted in lower NET occupancy compared with venlafaxine XR (doses up to 225 mg/day). In contrast to venlafaxine, paroxetine had no effect on HRV, as measured by changes in R-R interval during forced 10-second breaths and respiratory sinus arrhythmia (RSA) during paced breathing. Further comparisons of the effects of antidepressant medications on HRV are warranted.

Paroxetine and other SRIs have been implicated in precipitation of the syndrome of inappropriate antidiuretic hormone (SIADH), particularly in elderly individuals, which resolves on discontinuation of the medication (Strachan and Shepherd 1998). The potential for paroxetine-induced hyponatremia

was prospectively evaluated in a 12-week open trial involving depressed male and female subjects between the ages of 63 and 90 years (Fabian et al. 2004). Hyponatremia, defined as plasma sodium levels lower than 135 mEq per liter, developed in 9 of the 75 total subjects (12%), in most cases within 10 days of initiation. Risk factors for developing hyponatremia were low body mass index (BMI) and low starting plasma sodium levels. These results underscore the importance of monitoring electrolytes closely in geriatric patients treated with paroxetine and other antidepressants.

Discontinuation Syndrome

Following closely on the heels of the widespread use of SRIs came the realization that abrupt discontinuation of these drugs often precipitates the emergence of unpleasant symptoms. This constellation of psychological and physical symptoms, which may appear upon treatment interruption, is referred to as the "SRI discontinuation syndrome." Postmarketing data gathered in the United Kingdom reported the occurrence of withdrawal-related events to be greater in paroxetine-treated patients (5.1% of total adverse drug events) than in patients treated with sertraline (0.9%), fluvoxamine (0.4%), or fluoxetine (0.2%), with a mean duration of 10.2 days (Price et al. 1996). Rosenbaum et al. (1998) compared paroxetine with fluoxetine and sertraline, following, on average, nearly 12 months of open-label treatment in 242 patients with major depression to assess the emergence of withdrawal symptoms in a double-blind, placebo-substitution fashion. The authors found paroxetine to be associated with a significantly greater mean score on the discontinuation-emergent signs and symptoms (DESS) checklist than both sertraline and fluoxetine. Both paroxetine and sertraline were associated with significant deterioration in depressive symptoms, as rated by the 28-item Ham-D and MADRS, during the 5- to 7-day placebo substitution. The most common symptoms attributed to paroxetine discontinuation were nausea, dizziness, insomnia, headache, and nervousness. Withdrawal in all groups was resolved upon subsequent reintroduction of medication.

These findings were confirmed in another blinded, placebo-substitution study, which reported a significantly greater total number of adverse events in paroxetine-treated patients with depression versus either fluoxetine or sertraline, as early as day 2 of active drug withdrawal (see Michelson et al. 2000). Similar liability was associated with paroxetine in terms of the 21-item Ham-D and State Anxiety Inventory scores, as well as changes in standing and orthostatic heart rate. Discontinuation was more recently compared between paroxetine and agomelatine, a mixed melatonergic and serotonergic agonist currently under FDA evaluation for the treatment of depression. In a double-blind, placebo-controlled discontinuation study, 192 depressed patients who had experienced sustained remission on either drug were randomly assigned to continue active treatment or to receive placebo for a 2-week follow-up period (Montgomery et al. 2004). During the first week postrandomization, placebo substitution resulted in considerable discontinuation symptoms in the paroxetine group (active dosage = 20 mg/day) but none in patients taking agomelatine (active dosage = 25 mg/day). These effects were not observed into the second week of discontinuation for either drug.

The studies noted above tested treatment discontinuation effects over a minimum of 5–8 days. Newer trials have evaluated the effects of shorter-term interruptions (3–5 days) similar to what a patient would experience if he or she were to inadvertently miss just a few doses. Following brief treatment interruption with placebo, Judge et al. (2002) found that paroxetine cessation led to significant discontinuation-emergent events, whereas fluoxetine-treated patients were not symptomatic. It was surmised that fluoxetine's long half-life conferred a protective effect during interruption. Paroxetine fared better during brief discontinuation in comparison with escitalopram. Measurements on the DESS checklist indicated that there were no significant differences between the two drugs when randomly replaced with placebo for 3- to 5-day periods (Baldwin et al. 2006), as both medications showed similar degrees of SRI withdrawal. The researchers did note that paroxetine (mean dosage = 26.3 mg/day) was significantly more likely to cause discontinuation side effects in comparison with

escitalopram (mean dosage = 13.9 mg/day) during a taper period at the end of the trial in which higher-dosed subjects in either group were switched to lower doses for a week and lower-dosed subjects were switched to alternate-day dosing for a week prior to complete cessation.

Results from these studies suggest that the abrupt cessation of paroxetine is associated with the SRI discontinuation syndrome in approximately one-third of patients. This syndrome has been attributed to the short half-life of paroxetine, relative to that of other SRIs, as well as to the lack of any active metabolites (Michelson et al. 2000). Symptoms occur as early as the second day after a missed dose and may persist for several days. To mitigate the emergence of withdrawal symptoms, practitioners are advised to gradually taper the dose of paroxetine when discontinuing this medication in their patients. Despite the potential for "withdrawal" reactions after abrupt discontinuation of paroxetine, venlafaxine, duloxetine, and other antidepressants, there is no clinical evidence for dose escalation, craving, or drug-seeking behavior associated with dependence liability or "addiction" (Inman et al. 1993; Johnson et al. 1998; Sharma et al. 2000).

Overdoses with paroxetine are rarely associated with morbidity or mortality, which stands in stark contrast to the situation with the TCAs, with their low therapeutic index, or venlafaxine (Buckley et al. 2003; Cheeta et al. 2004). In the clinical trials program prior to FDA registration of paroxetine, 16 patients had ingested an overdose (doses of up to 850 mg of paroxetine); all patients recovered uneventfully (Jenner 1992). A review examining the American Association of Poison Control Centers (AAPCC) and FDA adverse events databases, as well as a MEDLINE literature search, revealed a total of 28 fatalities involving paroxetine overdoses; however, in nearly all cases, either coingestants were involved or causality could not be ascertained (Barbey and Roose 1998). In the overwhelming majority of intentional overdoses of paroxetine, individuals recovered without incident. Consequently, paroxetine can be safely prescribed in patients in whom impulsivity and suicidality are present.

Pregnancy and Lactation

One of the most challenging questions faced by patients and health care practitioners in family planning is whether to initiate or continue antidepressant therapy during conception, pregnancy, and the postpartum period. In exploring the risk–benefit analysis, one needs to consider the potential teratogenic risk of exposure of the antidepressant to the infants against the risks to the unborn children of women with untreated depression during pregnancy.

Newborns of women with depression have been shown to have a disproportionately higher risk of lower birth weight, preterm delivery, and small size for gestational age (Steer et al. 1992). Additionally, women with depression have higher rates of smoking and alcohol consumption, which represent further risks to pregnancy outcome (Zuckerman et al. 1989). Laboratory animal studies have demonstrated no significant effects of paroxetine in offspring of exposed pregnant mice in terms of early developmental tasks, locomotor and exploratory behavior, or cognition (Christensen et al. 2000; Coleman et al. 1999). In human studies, placental passage of paroxetine from mothers to developing infants was assessed by comparing maternal serum SRI concentrations with those found in cord blood at the time of delivery (Hendrick et al. 2003b). Paroxetine and sertraline had lower ratios of umbilical cord–maternal serum drug concentrations compared with citalopram and fluoxetine. Furthermore, unlike fluoxetine and sertraline, paroxetine cord blood concentrations did not correlate with maternal dosing, suggesting that an increase in maternal medication dose during pregnancy will not necessarily be accompanied by a comparable increase in fetal paroxetine exposure.

Clinical studies of paroxetine in the setting of pregnancy suggest that gestational exposure might have transient negative effects on newborn infants, particularly if the mother is treated during the third trimester. A prospective cohort study compared perinatal outcomes of 55 pregnant mothers treated with paroxetine, at various doses, during the third trimester with those of 27 mothers treated with paroxetine during one or both of the first two trimesters. A third sample was a control group of 27

expectant females treated with other medications classified as nonteratogenic. In this trial, Costei et al. (2002) found that third-trimester paroxetine exposure was associated with significant increases in neonatal distress (odds ratio = 9.53) compared with the other two groups. The most commonly observed forms of distress were characterized as respiratory distress and hypoglycemia. Results like these have stirred debate among neonatologists as to whether newborn distress attributed to SRIs is a manifestation of toxicity or of withdrawal (Stiskal 2005). Numerous case reports and case series have described transient neonatal symptoms following in utero exposure to SRI antidepressants, and these include (but are not limited to) tremor, hypertonicity, irritability, and poor feeding (Knoppert et al. 2006). Large trials correlating neonatal distress symptoms with infant serum drug levels, however, have not been performed thus far with paroxetine. Reduced or absent CYP2D6 isoenzyme activity associated with high paroxetine concentrations and hyperserotonergic states has been suggested as a putative mechanism for infant distress in many cases (Laine et al. 2004). Conversely, it has also been argued that in view of paroxetine's short half-life, neonatal distress is more likely to be caused by an SRI discontinuation effect (Stiskal 2006). The question is somewhat muddied by the fact that both hyper- and hyposerotonergic states can result in similar symptoms in newborns, such as restlessness and rigidity (Einarson and Koren 2006). The differential diagnosis between SRI neonatal withdrawal and serotonergic symptoms has important ramifications, given that withdrawal would be optimally treated with an SRI. In contrast, such treatment may endanger babies exhibiting serotonin toxicity.

Another significant clinical question is whether paroxetine is associated with teratogenicity. The results of an unpublished study conducted by GlaxoSmithKline (Paxil) led the FDA to warn that paroxetine may increase the risk of major congenital malformations. In a retrospective analysis of data from two U.S. managed-care insurance databases, pregnancy outcomes from a sample of 3,581 gravid mothers (ages 12–49 years) who were taking antidepressants were studied (see GlaxoSmithKline 2005). Of the 18 total medications compared, including other SRIs, SNRIs, TCAs, and newer drugs, only paroxetine had an increased risk of malformations that was significantly greater than that of other antidepressants (odds ratio = 2.20). Several organ systems, including the gastrointestinal, genitourinary, and central nervous systems, were affected in similar proportions. The most common cardiovascular anomalies were ventricular septal defects. The study did not include pregnant women without antidepressant exposure; however, the accepted prevalence of major congenital malformations for all births in the United States is roughly 3%, while the absolute rate observed among first-trimester paroxetine-exposed infants in this study was 4%. A 1% increase in absolute risk over baseline translates to a need for 100 pregnant women to take paroxetine during the first trimester before additional harm would come to 1 infant. Limitations of this study include its retrospective design, lack of controls, lack of clinical details about individual cases, and the fact that it represents a post hoc secondary analysis.

These data are contradicted by several other trials that might be considered more scientifically valid, given their prospective nature. In a cohort study, Kulin et al. (1998) compared rates of major congenital malformations in 237 pregnant women treated with paroxetine, fluvoxamine, or sertraline and found no significant differences among the medication groups compared with control groups. More recently, Hendrick et al. (2003a) followed a total of 138 pregnant females treated with paroxetine, fluoxetine, or sertraline and found that rates of neonatal complications and congenital malformations were lower (1.4%) than rates in the general population. There were no significant differences among individual antidepressants when compared with each other. In a postmarketing surveillance report, 137 pregnancies involving maternal exposure to paroxetine were cited, with no infant abnormalities noted (Inman et al. 1993). In spite of these more reassuring data, the American College of Obstetricians and Gynecologists Committee on Obstetric Practice (2006) has recommended that paroxetine be avoided in women who are pregnant or planning to become pregnant.

Whether a woman decides to begin or continue paroxetine for the treatment of depression during pregnancy, the clinician is advised to monitor for relapse because one study demonstrated that higher

doses are often needed, especially in the early third trimester, to effect or maintain disease remission (Hostetter et al. 2000). Another time of increased risk is the postpartum period, when women are at a threefold higher relative risk for depression compared with non-child-bearing women (Cox et al. 1993). It is estimated that 13% of women develop depression following childbirth (O'Hara and Swain 1996). Furthermore, children of women with postpartum depression suffer from a number of social and intellectual impairments thought to be associated with compromised mother–infant bonding (A. Stein et al. 1991). Consequently, postpartum depression represents a significant health risk to both mother and child, and treatment with antidepressants during this period is often necessary.

Balanced against the established hazards associated with postpartum depression is the potential risk of exposure to antidepressants by the nursing infant. Breast feeding has long been advocated by health care providers for improved mother–child interaction and for infant health. In women with postpartum depression, the decision to breast feed, therefore, presents a dilemma. The emerging data appear to allay the concern of the exposure of SRIs, including paroxetine, to infants through breast milk. Like other antidepressants, paroxetine is secreted into breast milk, with greater concentrations found in hindmilk than foremilk (Ohman et al. 1999; Stowe et al. 2000). In a prospective study involving 16 women with postpartum depression treated with paroxetine, the sera of nursing infants were analyzed for the presence of paroxetine at several time points following maternal administration of paroxetine. Paroxetine was undetectable in all infants (Stowe et al. 2000). The authors cautioned against interpreting the findings to suggest that there is no infant exposure to paroxetine through breast milk because it is indeed found in breast milk, albeit in very low concentrations. Nevertheless, in view of the undetectable concentrations in infant blood, the exposure appears to be minimal. Furthermore, no obvious alterations in infant behavior or temperament have been observed in the breast-fed children of women treated with paroxetine in the short term. These data suggest that the benefits of breast-feeding can be maintained in women treated with paroxetine with minimal apparent risk of exposure to the infant. This issue is described in considerable detail elsewhere in this textbook (see Chapter 64, "Psychopharmacology During Pregnancy and Lactation").

DRUG–DRUG INTERACTIONS

Many medications rely on common metabolic processes for biotransformation into an active agent or inactive metabolite. As such, the likelihood that pharmacokinetic interactions among prescription and over-the-counter medications may lead to adverse outcomes becomes greater as medications with shared metabolic pathways are administered concurrently. As noted previously, paroxetine is primarily dependent on the CYP2D6 enzyme for conversion into its inactive metabolites (Hiemke and Härtter 2000). Paroxetine is not only a substrate for this system but also an inhibitor; therefore, other drugs that use this hepatic enzyme are potentially subject to decreased clearance and subsequent increased plasma concentrations (Sindrup et al. 1992b). Concern is greatest for potential drug–drug interactions when the affected medication has a low therapeutic index.

Medications that are CYP2D6 dependent include many antipsychotics, TCAs, type IC antiarrhythmics, β-adrenergic agents, trazodone, and dextromethorphan (Nemeroff et al. 1996). Most reports of interactions between these medications and paroxetine are published as case reports from which firm conclusions regarding causality cannot be drawn (Lane 1996). In regard to the TCAs, Brøsen et al. (1993) and Alderman et al. (1997) demonstrated, in prospective studies, that desipramine concentrations increased by 364% and 358%, respectively, when coadministered with paroxetine. Imipramine levels are also increased with the coadministration of paroxetine (Albers et al. 1996).

Antipsychotics are often prescribed with paroxetine in the treatment of psychotic depression and in the treatment of negative symptoms in schizophrenia or as augmentation therapy in patients with primary mood disorders. Paroxetine does not appear to potentiate the sedative effects of haloperidol (Cooper et al. 1989). Dystonia resulting from the combination of paroxetine and haloperidol has been reported (Budman et al. 1995). In one prospective study, clozapine levels increased by an average of

40% over controls when coadministered with SRIs, including paroxetine, at a mean dose of 31.2 mg (Centorrino et al. 1996). In another study using a lower dose of paroxetine (20 mg), no significant increases in clozapine concentrations were noted (Wetzel et al. 1998). These findings indicate that caution should be exercised when paroxetine and clozapine are prescribed together, particularly at higher doses of paroxetine. Case reports have demonstrated possible exaggerated extrapyramidal side effects when paroxetine was administered with perphenazine, molindone, and pimozide (Horrigan and Barnhill 1994; Malek-Ahmadi and Allen 1995; Ozdemir et al. 1997).

A number of medications that are bound to plasma proteins are capable of displacing or being displaced by highly protein-bound drugs, such as paroxetine, resulting in a potentially significant increase in the free concentration of the drug, although this mechanism rarely, if ever, is clinically meaningful (Preskorn 1993). In a prospective study with 27 patients, 5 patients developed mild bleeding when paroxetine was added to ongoing treatment with warfarin, although concentrations of warfarin and paroxetine, as well as prothrombin time, did not change significantly (Bannister et al. 1989). Although an explanation for an increased propensity for bleeding is unclear, it is recommended that anticoagulation parameters be carefully monitored when warfarin and paroxetine are coprescribed. Digoxin levels are unaffected by paroxetine treatment (Bannister et al. 1989), and lithium concentrations are also unchanged by paroxetine administration (Haenen et al. 1995).

In prospective studies involving the antiepileptic/mood stabilizers valproate and carbamazepine, as well as the anticonvulsant phenytoin, coadministration with paroxetine did not cause any significant changes in plasma levels of these drugs (Andersen et al. 1991; Kaye et al. 1989). In contrast, both phenytoin and carbamazepine have been shown to decrease plasma paroxetine concentrations by 28% (Kaye et al. 1989) and 55% (Hiemke and Härtter 2000), respectively. Valproate may increase plasma paroxetine concentrations (Andersen et al. 1991). Cimetidine, which is a potent inhibitor of the CYP2D6 isoenzyme, has been shown to result in a 50% elevation of paroxetine concentrations (Bannister et al. 1989). The clinical significance of the overall deviations in serum paroxetine concentration at steady state caused by these agents is minor because of wide interindividual pharmacokinetic variability, high therapeutic index, and lack of a concentration–efficacy relationship with paroxetine (Gunasekara et al. 1998).

Sedation is a possible side effect associated with barbiturates, benzodiazepines, and ethanol. Paroxetine does not potentiate the psychomotor effects of amobarbital, oxazepam, or alcohol (Cooper et al. 1989). No clinical or pharmacokinetic interaction was noted when paroxetine and diazepam were coadministered in a prospective study (Bannister et al. 1989).

Combination of medications that enhance serotonergic activity may result in the so-called serotonin syndrome, which may manifest as agitation, myoclonus, hyperreflexia, diarrhea, sweating, delirium, fever, elevated blood pressure, and possibly death (Weiner et al. 1997). Following case reports describing the emergence of this syndrome with the combination use of fluoxetine and MAOIs, the concomitant use of MAOIs with any of the SRIs is absolutely contraindicated, and a washout period of 14 days is recommended when switching from one agent to another (Gunasekara et al. 1998; Weiner et al. 1997). Evidence for the serotonin syndrome with paroxetine, in combination with other drugs, has been documented in case reports for moclobemide (Hawley et al. 1996), nefazodone (John et al. 1997), dextromethorphan (Skop et al. 1994), imipramine (Weiner et al. 1997), trazodone (Reeves and Bullen 1995), and others. The combination of SRIs and sumatriptan, a serotonin$_{1D}$ (5-HT$_{1D}$) receptor agonist used in the treatment of migraine, was previously discouraged because of the theoretical risk of precipitation of the serotonin syndrome; however, a series of six cases, one involving paroxetine, of concurrent sumatriptan and SRI administration demonstrated no adverse events (Leung and Ong 1995). This lack of interaction has been confirmed in a prospective trial (Franklin et al. 1996).

Overall, paroxetine may be safely administered with other medications, as clinically indicated. Coadministration with an MAOI is absolutely contraindicated, and careful monitoring is advised when

TCAs, warfarin, and clozapine are used in conjunction with paroxetine. As with any medication, clinicians are advised to minimize polypharmacy and remain vigilant to the possibility of drug–drug interactions (see Table 15–2 for the important drug–drug interactions with paroxetine).

TABLE 15–2. Potential drug–drug interactions involving paroxetine

Monoamine oxidase inhibitors	Clinically significant
Tricyclic antidepressants	Clinically significant
Type IC antiarrhythmics	Probably significant
β-Adrenergic antagonists	Probably significant
Antiepileptic agents	Probably significant
Cimetidine	Probably significant
Typical antipsychotics	Possibly significant
Warfarin	Possibly significant
Clozapine	Inconclusive
Lithium	Not clinically significant
Digoxin	Not clinically significant

CONCLUSION

Paroxetine has been demonstrated to be an effective treatment for several psychiatric disorders, including major depression and virtually all of the anxiety disorders. It is well tolerated with convenient once-daily dosing and is available in both IR and CR formulations. Most patients can expect symptomatic relief within 4 weeks, and some patients as early as 2 weeks. Concern for pharmacokinetic interactions with other drugs is minimal, although concomitant MAOI use is contraindicated. Overdosage rarely results in significant toxicity, rendering paroxetine a judicious choice among available psychotropics for the impulsive or suicidal patient. Paroxetine should be used cautiously in the treatment of pediatric anxiety disorders and sparingly in child and adolescent patients with depression. Its use in pregnancy remains controversial and requires more data to resolve safety concerns. In the postpartum setting, however, nursing very likely poses a negligible exposure risk to infants of mothers receiving treatment with paroxetine.

Paroxetine, with its wide application and favorable safety profile, represents an important member of the SRI class of drugs, although it appears to behave as an SNRI at higher doses. It continues to be evaluated for efficacy in the treatment of other psychiatric and nonpsychiatric disorders.

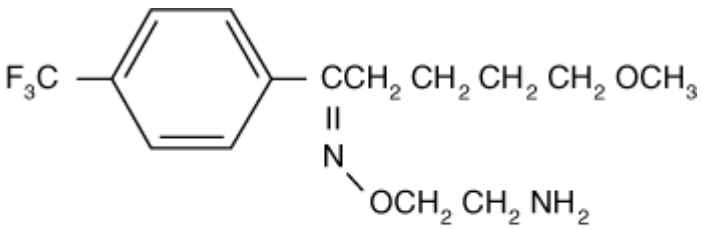
Chapter 16. Fluvoxamine



FLUVOXAMINE: INTRODUCTION

Fluvoxamine is a member of the selective serotonin reuptake inhibitor (SSRI) family of drugs. Initially manufactured by Duphar Laboratories in the United Kingdom in 1971, fluvoxamine was registered as an antidepressant in Switzerland in 1983, becoming the first drug in the now hugely popular SSRI class to reach the market (Freeman 1991). Since its introduction, fluvoxamine has undergone a wide range of trials to assess its therapeutic potential in depression and across several anxiety disorders, including obsessive-compulsive disorder (OCD). Fluvoxamine has been available in the United States since 1994, when it received U.S. Food and Drug Administration (FDA) approval for the treatment of OCD (Ware 1997). More than 28 million people worldwide have been treated with fluvoxamine (Buchberger and Wagner 2002).

STRUCTURE–ACTIVITY RELATIONS

Fluvoxamine belongs to the 2-aminoethyl oxime ethers of the aralkyl ketones, a unique chemical series unrelated to tricyclic antidepressants or other SSRIs. Fluvoxamine maleate is chemically identified as 5-methoxy-4'-(trifluoromethyl) valerophenone-(E)-O-(2-aminoethyl) oxime maleate (1:1). Its empirical formula is $C_{15}H_{21}O_2N_2F_3.C_4H_4O_4$, and its molecular weight is 434.4. Unlike the other SSRIs, fluvoxamine does not have an asymmetric carbon and hence does not have a chiral center or exist in stereoisomers. It is a whitish, odorless crystalline powder that is only sparingly soluble in water. It possesses local irritant properties that preclude its parenteral use ("Fluvoxamine" 2002). Figure 16–1 shows the molecular structure of fluvoxamine.

MECHANISM OF ACTION

Like other SSRIs, fluvoxamine binds to the presynaptic serotonin transporter (SERT) and prevents it from absorbing serotonin back into the presynaptic terminals, where it is metabolized by monoamine oxidases or stored in secretory vesicles. This has the net effect of increasing serotonin in the synaptic cleft. How these actions translate into efficacy for depression or anxiety remains the subject of investigation, especially because clinical improvement typically takes several weeks, whereas the drug's effect in enhancing monoamine neurotransmission is almost immediate. As a result, downstream mechanisms have been hypothesized to explain the therapeutic effects of SSRIs. These

mechanisms include 5-HT_{1A} autoreceptor desensitization (Stahl 1998), increased sensitivity of the D_2-like receptors in the nucleus accumbens (Gershon et al. 2007), enhanced neurogenesis in the hippocampus (Dranovsky and Hen 2006), cyclic adenosine monophosphate (cAMP)–mediated activation of the pathway for cAMP response element–binding protein brain-derived neurotrophic factor (CREB-BDNF) (Gershon et al. 2007), and individual pharmacogenomic factors that determine how SSRIs interact with specific gene variants of the serotonin transporter (Mancama and Kerwin 2003).

Recent research has examined the putative role of the sigma-1 receptor in the mechanism of action of SSRIs and the pathophysiology of various psychiatric illnesses, including major depression. Sigma-1 receptors are thought to exert potent modulatory effects on several neurotransmitter systems, including the serotonergic, glutamatergic, noradrenergic, and dopaminergic pathways. Studies using positron emission tomography have demonstrated that fluvoxamine's affinity for the sigma-1 receptor in the human brain is higher than that of any of the other SSRIs (Ishikawa et al. 2007).

PHARMACOLOGICAL PROFILE

Although the data are somewhat inconsistent, in vitro and in vivo studies suggest that fluvoxamine is a more potent inhibitor of serotonin reuptake than the tricyclic antidepressants, including clomipramine, but less potent than the other SSRIs. Fluvoxamine also is very selective for the human serotonin transporter (K_i = 2.3 nmol/L) and has only minimal affinity for the human norepinephrine and dopamine transporters (K_i = 1,427 and 16,790 nmol/L, respectively) (Owens et al. 2001). Fluvoxamine also has minimal affinity for the muscarinic, α_1-adrenergic, histaminic, and 5-HT_{2C} receptors and possesses no monoamine oxidase–inhibiting properties (Lapierre et al. 1983; Owens et al. 2001; Palmer and Benfield 1994; Ware 1997; Westenberg and Sadner 2006).

PHARMACOKINETICS AND DISPOSITION

After oral administration, fluvoxamine is almost entirely absorbed from the gastrointestinal tract, regardless of the presence of food (Van Harten 1995). However, despite complete absorption, oral bioavailability (i.e., the amount available in systemic circulation in intact form) is only 53% (DeVane 2003; DeVane and Gill 1997) due to first-pass hepatic metabolism. Following single-dose administration, peak plasma concentrations are reached within 2–8 hours, and steady-state concentration is achieved within 10 days (Van Harten 1995). At steady state, fluvoxamine appears to display nonlinear pharmacokinetics over its therapeutic dosage range, with disproportionately higher plasma concentrations at higher dosages. Plasma concentration, however, shows no consistent correlation with efficacy or severity of side effects, suggesting that plasma concentration monitoring is of limited value.

The mean half-life of fluvoxamine is 15 hours (range: 8–28 hours). This relatively short half-life makes twice-daily dosing preferable. Although psychoactive medications with relatively short half-lives are more likely to cause discontinuation syndromes if stopped abruptly, this effect appears to be rare with fluvoxamine (Buchberger and Wagner 2002), especially in comparison with paroxetine, an SSRI with a somewhat longer half-life but worse discontinuation problems (Pae and Patkar 2007). A possible explanation for this difference is provided from fluorine-19 magnetic resonance spectroscopy (^{19}F MRS) data showing that fluvoxamine is more slowly eliminated from the brain than from plasma (mean ratio of brain elimination half-life to plasma half-life = 2.4) (Strauss et al. 1998).

Because of its lipophilicity, fluvoxamine is widely distributed and is found in higher concentrations in the brain and other major organs than in plasma (Benfield and Ward 1986). For this reason, it is unnecessary to give replacement doses of fluvoxamine to patients receiving hemodialysis for severe renal dysfunction: re-equilibration should occur, with drug being recruited from tissues to plasma (DeVane and Gill 1997).

Compared with other SSRIs, fluvoxamine's rate of protein binding is relatively low, at 77% (DeVane

and Gill 1997). Only escitalopram has a lower protein-binding rate (56%) (Rao 2007). Low protein binding can be advantageous, because interactions through drug displacement are less likely to occur when multiple medications that are bound to the same proteins are coadministered. Protein binding is also important in determining the hemodialyzability of drugs.

At least 11 products of fluvoxamine hepatic metabolism have been identified, but none are thought to be pharmacologically active (DeVane and Gill 1997; Palmer and Benfield 1994; Ruijten et al. 1984). Metabolism is thought to occur primarily through oxidative demethylation, although the exact enzyme systems involved in fluvoxamine breakdown have not been fully elucidated. Only minimal amounts of fluvoxamine (3%) are excreted unchanged by the kidneys, suggesting that renal impairment should not significantly alter fluvoxamine's pharmacokinetics (Van Harten 1995).

Because hepatic clearance is decreased in patients with liver disease and in elderly patients, dosage adjustments are sometimes necessary in these populations (DeVane and Gill 1997; Van Harten et al. 1993). No gender-based differences in fluvoxamine concentration seem to exist in adults, although most pharmacokinetic data were obtained from male subjects (DeVane and Gill 1997). Studies examining the pharmacokinetics of fluvoxamine among children and adolescents have found a higher area under the curve (AUC) in children compared with adolescents, with the difference being more pronounced among female children, suggesting that lower drug dosages may be sufficient in this group. No appreciable pharmacokinetic differences were observed between the adolescent and adult groups ("Fluvoxamine" 2002).

INDICATIONS AND EFFICACY

Depression

The first trial to assess the role of fluvoxamine in the treatment of depression dates back to 1976. We identified 38 randomized, single- or double-blind studies conducted since then to test the antidepressant efficacy of fluvoxamine against placebo, SSRIs (sertraline, fluoxetine, citalopram, and paroxetine), serotonin-norepinephrine reuptake inhibitors (SNRIs; venlafaxine and milnacipran), tricyclic antidepressants (clomipramine, imipramine, desipramine, amitriptyline, and nortriptyline), tetracyclic antidepressants (mianserin and maprotiline), and a reversible inhibitor of monoamine oxidase (moclobemide). These trials varied widely in design, including the diagnostic and inclusion criteria utilized, the requirement for a washout period before initiation of study drug, and the way treatment response was defined. However, taken together, these studies support the efficacy and safety of fluvoxamine in the treatment of mild, moderate, and severe depression—including psychotic depression—across all age groups and in both inpatient and outpatient settings (Fukuchi and Kanemoto 2002; Haffmans et al. 1996; Kiev and Feiger 1997; Otsubo et al. 2005; Rapaport et al. 1996; Rossini et al. 2005; Ware 1997; Zanardi et al. 2000; Zohar et al. 2003). Among all studies, none showed fluvoxamine to be inferior in efficacy to another active comparator when a priori response criteria were applied. Study durations ranged from 4 to 7 weeks, and dosages ranged from 50 to 300 mg/day. Furthermore, the benefits from fluvoxamine seem to be sustained over the long term. In a double-blind, placebo-controlled study assessing the efficacy of fluvoxamine continuation treatment, fluvoxamine at 100 mg/day was significantly superior to placebo in preventing symptom recurrence over the 1-year maintenance period (Terra and Montgomery 1998).

Obsessive-Compulsive Disorder in Adults

Clomipramine is the only tricyclic antidepressant with established efficacy in OCD. Given that clomipramine is also the most serotonergic drug in its class, its efficacy supported the hypothesis that serotonin pathways are implicated in the pathophysiology of OCD. When fluvoxamine, a drug that is more potent and selective for the serotonin transporter than clomipramine, became available in the early 1980s, researchers quickly became interested in exploring its potential efficacy in the treatment of OCD. The first formal testing took place in 1987: a positive single-blind trial of 10 subjects with OCD

(Price et al. 1987). Since then, multiple randomized studies have established fluvoxamine's efficacy and safety in the treatment of OCD, regardless of the presence or severity of comorbid depression. These trials have compared fluvoxamine with placebo, clomipramine, and other SSRIs.

In randomized, double-blind comparisons with placebo, subjects were given fluvoxamine 100–300 mg/day for 6–10 weeks. Significant improvements in scores on the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) and other primary and secondary outcome measures were observed after a 3- to 4-week delay. Overall, response rates ranged from 38% to 52% (vs. 0% to 18% for placebo) (Figgitt and McClellan 2000).

We identified five published double-blind comparisons of fluvoxamine and clomipramine, both dosed at ≤300 mg/day, involving a total of 531 subjects and lasting 9–10 weeks (Figgitt and McClellan 2000; Freeman et al. 1994; Koran et al. 1996; Milanfranchi et al. 1997; Mundo et al. 2000, 2001). All of these studies demonstrated equal efficacy for the two agents (range of response rates: 56%–85% for fluvoxamine and 53%–83% for clomipramine). In the largest of these comparisons, 227 subjects meeting DSM-III-R (American Psychiatric Association 1987) criteria for OCD were randomly assigned to either fluvoxamine or clomipramine (both at 150–300 mg/day) for 10 weeks. At study end, rates of response (defined as ≤35% improvement in Y-BOCS score) were similar for the two drugs (62% for fluvoxamine vs. 65% for clomipramine, *P* = NS). However, fluvoxamine was better tolerated than clomipramine, as evidenced by its much lower rate of premature withdrawal due to side effects (8% for fluvoxamine vs. 16% for clomipramine) (Mundo et al. 2001). Only one published study has compared fluvoxamine with other SSRIs. This small 10-week single-blind study of 30 subjects randomly assigned to fluvoxamine, paroxetine, or citalopram suggested similar efficacy among the three agents (Mundo et al. 1997).

Data also suggest that long-term maintenance treatment with fluvoxamine following acute response is protective against OCD relapse. A 2-year open-label follow-up study in 130 subjects who had responded to a 6-month course of fluvoxamine 300 mg/day, clomipramine 150 mg/day, or fluoxetine 40 mg/day showed that for all three agents, maintenance treatment at full or half dosages was significantly superior to treatment discontinuation in preventing OCD relapse (Ravizza et al. 1996).

Use of fluvoxamine in the short term has been reported to enhance the efficacy of behavioral therapy in patients with OCD. In a 9-week study that compared 58 evaluable subjects who received exposure therapy in combination with fluvoxamine (≤300 mg/day) or placebo, the response rate (≥35% reduction in Y-BOCS score) was higher in the fluvoxamine group than in the placebo group (87.5% vs. 60%, *P* ≤0.05) (Hohagen et al. 1998). In another study in 60 subjects with OCD, fluvoxamine (≤300 mg/day) combined with either antiexposure or exposure therapy significantly reduced daily rituals, compared with placebo combined with exposure therapy (*P* = 0.02), in the first 2 months of treatment, although this superior response did not persist at subsequent follow-up points (Cottraux et al. 1993).

The long-term benefit of fluvoxamine relative to behavioral treatment was explored in a study of 102 subjects recruited 5 years after completing two 16-week studies that tested the effectiveness of cognitive therapy alone, exposure response prevention alone, or cognitive-behavioral therapy in combination with fluvoxamine (Van Oppen et al. 2005). The original sample included 122 subjects. At the 5-year follow-up point, the clinical benefits to patients who had received cognitive therapy alone, exposure response prevention alone, or cognitive-behavioral therapy with fluvoxamine were maintained. Significantly more subjects who were still on antidepressants had received fluvoxamine in the controlled trials, suggesting that subjects who were randomized to the fluvoxamine group in the original trials tended to stay on the drug. However, more than 63% of subjects had received some form of additional psychological or pharmacological treatment in the intervening 5 years, making the results difficult to interpret. More than half (53.5%) of subjects no longer met DSM-III-R criteria for OCD at follow-up, and only 5% showed signs of deterioration.

Obsessive-Compulsive Disorder in Children and Adolescents

OCD often manifests in childhood or adolescence. Early intervention could potentially alter what is often a chronic waxing and waning course, but few pharmacological options for OCD have been adequately studied in this patient population. The safety and efficacy of fluvoxamine 50–200 mg/day were assessed in a 10-week double-blind, placebo-controlled multisite study involving 120 subjects ages 8–17 years with DSM-III-R–defined OCD. Response was defined as a reduction of at least 25% in the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) score. Mean CY-BOCS scores were significantly lower in the fluvoxamine group than in the placebo group as early as week 1 and remained lower at weeks 2, 3, 4, 6, and 10 ($P < 0.05$). End-of-study response rates were 42% for the fluvoxamine group and 26% for the placebo group ($P = 0.065$). The most common side effects (>10% rate than placebo) were insomnia and asthenia (Riddle et al. 2001).

Panic Disorder

SSRIs are considered a first-line treatment for panic disorder. Several small randomized, double-blind, placebo-controlled studies lasting 6–8 weeks were conducted in the 1990s to assess the efficacy of fluvoxamine 50–300 mg/day in the treatment of subjects with DSM-III-R–defined panic disorder. These studies generally showed favorable results compared with placebo, reporting reductions of 54%–100% in the weekly rate of panic attacks (Figgitt and McClellan 2000). More recently, a large multisite study was conducted in 188 subjects who met DSM-III-R criteria for panic disorder with or without agoraphobia, recruited from four centers in the United States. Subjects were randomly assigned to receive 8 weeks of fluvoxamine 100–300 mg/day or placebo. At study end, significantly more subjects in the fluvoxamine group were free from panic attacks (69% vs. 46%, $P = 0.002$). An early onset of action was also seen: between-group differences in the proportion of subjects free from panic attacks at week 1 were significant in favor of fluvoxamine ($P < 0.05$) (Asnis et al. 2001).

Limited comparative data suggest equal efficacy between fluvoxamine and the tricyclic antidepressant imipramine (both at dosages ≤300 mg/day) in the treatment of panic disorder, as well as a possible potentiating effect of fluvoxamine when combined with cognitive or exposure therapy (Figgitt and McClellan 2000).

Social Anxiety Disorder

Selective serotonin reuptake inhibitors are considered the first-line treatment for social anxiety disorder (social phobia). The largest double-blind, placebo-controlled study to assess the effectiveness of fluvoxamine in the treatment of social anxiety disorder recruited 92 subjects meeting DSM-IV (American Psychiatric Association 1994) criteria for social phobia from four centers in the United States (M. B. Stein et al. 1999). Subjects were randomly assigned to receive fluvoxamine (50–300 mg/day) or placebo. The primary outcome measure was the proportion of subjects at study end with a rating of much or very much improved on the global improvement item of the Clinical Global Impressions Scale. Secondary outcome measures included the Liebowitz Social Anxiety Scale (LSAS). Using last-observation-carried-forward analysis to interpret results from 86 evaluable subjects, the investigators determined that significantly more patients receiving fluvoxamine than receiving placebo had responded (43% vs. 23%, $P = 0.04$). The decrease in Liebowitz Social Anxiety Scale score was 22 for the fluvoxamine group versus 8 for placebo group (M. B. Stein et al. 1999). More recently, a controlled-release (CR) formulation of fluvoxamine showed similarly good results in two randomized, double-blind studies (Davidson et al. 2004; Westenberg et al. 2004). In February 2008, this formulation was approved by the FDA for the treatment of social anxiety disorder and OCD.

Posttraumatic Stress Disorder

Small open-label studies suggest a role for fluvoxamine in the treatment of posttraumatic stress disorder (PTSD) (Davidson et al. 1998; Figgitt and McClellan 2000; Marmar et al. 1996; Tucker et al.

2000). Twenty-four Dutch World War II veterans with chronic PTSD showed significant improvement on a PTSD self-rating scale after a 12-week course of fluvoxamine at ≤300 mg/day ($P = 0.04$). Improvement was seen across several key PTSD symptoms, including reductions in nightmares, flashbacks, insomnia, and survival guilt (De Boer et al. 1992). More recently, a 14-week open-label trial of fluvoxamine (100–300 mg/day) in the treatment of 15 U.S. veterans with combat-related PTSD reported a statistically significant decrease at study end in the Clinician-Administered PTSD Scale (CAPS) total score ($P < 0.001$), as well as in the intrusion and avoidance subscales (both $P < 0.001$) (Escalona et al. 2002).

Obsessive-Compulsive Spectrum Disorders

Because of their established role in the treatment of OCD, SSRIs (including fluvoxamine) have been tested in other disorders considered to be part of the obsessive-compulsive spectrum, including trichotillomania, compulsive buying disorder, pathological gambling, and body dysmorphic disorder. These conditions share with OCD features such as intrusive, anxiety-laden thoughts and a drive to perform a pathological behavior that can help relieve anxiety. However, like other SSRIs, fluvoxamine has produced inconsistent results when tested in these disorders.

For instance, in an open-label study of fluvoxamine in subjects with compulsive buying disorder, 9 of 10 participants improved (Black et al. 1997). However, two double-blind, placebo-controlled studies failed to show benefit for fluvoxamine over placebo (Black et al. 2000; Ninan et al. 2000).

Similarly, one double-blind study with placebo crossover and one single-blind study ($N = 15$ and 10, respectively) in subjects with pathological gambling suggested that fluvoxamine might be beneficial (Hollander et al. 1998, 2000). However, a larger 6-month double-blind, placebo-controlled study in 32 subjects with pathological gambling failed to show a separation between fluvoxamine 200 mg/day and placebo (Blanco et al. 2002).

Body dysmorphic disorder (or delusional disorder, somatic type) has also been conceptualized to be part of the obsessive-compulsive spectrum of conditions. Three prospective open-label trials of fluvoxamine (≤300 mg/day for 10–16 weeks) involving a total of 75 subjects reported response rates of 63%–67% (Perugi et al. 1996; Phillips et al. 1998, 2001). These findings, however, have not been confirmed in double-blind studies.

Finally, a 12-week open-label study of fluvoxamine 300 mg/day in 21 subjects with trichotillomania found only minor differences on some measures of improvement between pre- and posttreatment (Stanley et al. 1997).

Eating Disorders

Bulimia nervosa is characterized by binge-eating episodes that are accompanied by pathological compensatory measures, including self-induced vomiting, laxative abuse, fasting, and excessive exercising. Seventy-two subjects with bulimia nervosa treated successfully with psychotherapy were randomly assigned to receive fluvoxamine (100–300 mg/day) or placebo and were followed for 12 weeks. Fluvoxamine was significantly superior to placebo in protecting against relapse to bulimic behavior during the study period ($P < 0.05$) (Fichter et al. 1996). A small 12-week double-blind, placebo-controlled study in 12 subjects with DSM-IV–defined bulimia nervosa suggested that fluvoxamine 200 mg/day was superior to placebo for acute treatment of bulimia nervosa (Milano et al. 2005).

The hallmark of binge-eating disorder is recurrent binge-eating episodes without accompanying purging. A 9-week double-blind, placebo-controlled study in 85 subjects with DSM-IV–defined binge-eating disorder found that fluvoxamine (50–300 mg/day) was significantly more effective than placebo in reducing binge-eating frequency ($P < 0.05$) (Hudson et al. 1998).

SIDE EFFECTS AND TOXICOLOGY

The SSRIs, including fluvoxamine, represent an improvement in tolerability over the tricyclic antidepressants, including less likelihood of anticholinergic, cardiotoxic, and epileptogenic side effects, as well as relative safety in overdose. With the goal of assessing safety, data from 34,587 patients enrolled in 66 postmarketing fluvoxamine clinical studies were combined in a global database. The majority of these studies were conducted in patients with depression. Some studies lacked a placebo arm or relied on voluntary reporting of side effects by subjects, which likely led to underestimation of side effects. Fluvoxamine dosages employed in these studies ranged from 50 to 300 mg/day taken over 4–52 weeks. Both "adverse events" and "serious adverse events" were analyzed (Wagner et al. 1994). Of subjects enrolled in the analysis of the postmarketing trials, 14% discontinued prematurely because of side-effect rates. The most frequent reasons for early discontinuation due to adverse events were nausea and vomiting (4.6% and 1.7%, respectively). In the sample overall, the adverse events reported at greater than 5% incidence were nausea, somnolence, and asthenia (15.7%, 6.4%, and 5.1%, respectively). The rate of weight gain was only 1%. Sexual side effects were not mentioned in the analysis, suggesting that fewer than 1% of subjects in these studies reported such effects (only side effects with >1% incidence were listed), although a separate prospective open-label study specifically designed to assess the incidence of SSRI-induced sexual dysfunction in men (n = 152) and women (n = 192) showed statistically similar rates for fluvoxamine, fluoxetine, sertraline, and paroxetine (range: 54.4%–64.7%) (Montejo-Gonzales et al. 1997). "Serious adverse events" were defined, according to FDA guidelines, as events that are fatal, life-threatening, permanently disabling, necessitate hospitalization, or lead to cancer, overdose, or congenital anomaly. Approximately 2% of the fluvoxamine-exposed population reported at least one serious adverse event. The most commonly reported adverse event was hospitalization (1.6%), followed by emergence of suicidality (0.66%—which includes suicide attempts in 0.3%). The rate of completed suicide was 0.03%. The incidence of seizures was only 0.005% (Wagner et al. 1994).

Other studies have assessed changes in laboratory values or vital signs in fluvoxamine-exposed subjects. One database of standard metabolic lab results and complete blood counts was compiled from 1,630 subjects enrolled in 17 studies. Another database assessed vital signs in 9,689 subjects enrolled in 37 studies. No consistent treatment-related changes were seen in either study (Wagner et al. 1994).

Postmarketing surveillance usually relies on spontaneous self-reports from patients, health care providers, and health authorities. Because it covers millions of exposed patients in varied clinical settings, such surveillance can reveal a drug's rare side effects, although it also tends to underestimate common, expected side effects that often go unreported. A review covering 17 years of postmarketing surveillance of patients exposed to fluvoxamine (Buchberger and Wagner 2002) analyzed 6,658 individual reports, including 16,110 adverse drug reactions. The frequency of death while taking fluvoxamine was calculated at 0.9 death per 100,000 patients. Suicide, mostly by overdose, was the cause of death in nearly half of these cases, but only 1.2% of overdoses involved fluvoxamine alone. The rate of suicidality (ideation, attempts, and completed suicides) was estimated at 2.81 events per 100,000 patients. Drug interactions were reported at a rate of 0.85 case per 100,000 patients; the most commonly reported interaction was with clozapine. Switch to mania and discontinuation syndrome were also rare, occurring at rates of 0.47 and 0.38 events per 100,000 patients, respectively. Serotonin syndrome was even less frequent (Buchberger and Wagner 2002).

DRUG–DRUG INTERACTIONS

Fluvoxamine's inhibitory effect on some cytochrome P450 (CYP) enzymes has been well documented. Fluvoxamine is a potent inhibitor of CYP1A2. Drugs partially metabolized by CYP1A2 whose levels may rise as a result of fluvoxamine's inhibition of this isozyme include tizanidine, tertiary-amine tricyclic

antidepressants (imipramine, amitriptyline, clomipramine), clozapine, tacrine, theophylline, propranolol, and caffeine. For this reason, it has been recommended that doses of theophylline and clozapine be reduced when either of these agents is coadministered with fluvoxamine (DeVane and Gill 1997).

Fluvoxamine also inhibits CYP2C19 and CYP3A4 (DeVane and Gill 1997). CYP2C19 metabolizes warfarin, and elevations in warfarin concentration have been reported in patients taking fluvoxamine. As a result, closer monitoring of anticoagulation status is indicated in these patients. Alprazolam and diazepam are metabolized in part through CYP3A4, and fluvoxamine has been shown to prolong their elimination (DeVane and Gill 1997). Carbamazepine is partially metabolized through CYP3A4, and elevated carbamazepine levels have been documented in patients concomitantly taking fluvoxamine (Palmer and Benfield 1994). Other drugs metabolized in part through CYP3A4 that may be affected by fluvoxamine include pimozide, methadone, and thioridazine. Also, because of the serious QT interval prolongation that can occur when terfenadine or astemizole is combined with the potent CYP3A4 inhibitor ketoconazole, it is recommended that fluvoxamine be avoided in patients who require these antihistamines (DeVane and Gill 1997). Fluvoxamine is contraindicated for use with thioridazine, tizanidine, pimozide, alosetron, ramelteon, and MAOIs (Fluvoxamine CR 2008).

No appreciable drug interactions exist between fluvoxamine and lithium, digoxin, or alcohol ("Fluvoxamine" 2002).

PREGNANCY AND LACTATION

Pregnancy and the postpartum are considered to be relatively high-risk periods for depressive episodes. The decision to administer antidepressant treatment to a pregnant or breast-feeding woman can be difficult and should involve careful evaluation of the severity of the symptoms, the patient's psychiatric history (including her history during and following previous pregnancies), self-care while pregnant, the effects of depression on mother–infant bonding, and the availability of other treatments and support. The FDA lists fluvoxamine under Pregnancy Category C, meaning that risk to the fetus cannot be ruled out, and only limited fluvoxamine-specific data exist to help guide clinicians and patients. One study tried to assess teratogenic or perinatal effects relating to fluvoxamine exposure in utero in 92 pregnant women, 37 of whom were taking concomitant medications. No significant difference in adverse events was seen compared with the control group (Gentile 2005).

Very limited case reports, covering only 8 infants exposed to fluvoxamine through lactation, have been published. No adverse events were reported in any of the infants. Fluvoxamine was not detected in 4 exposed infants in one case report, and another suggested normal development 2–3 years following lactation in 2 infants (Gentile 2005).

CONCLUSION

In 1983, fluvoxamine became the first member of the hugely popular SSRI family to be available on the market. Since then, more than 28 million adults and children have been prescribed fluvoxamine for a variety of psychiatric conditions including major depression, OCD, panic disorder, social anxiety disorder, impulse-control disorders, and eating disorders. Considering the number and size of double-blind, placebo-controlled clinical trials conducted, major depression and OCD have received the most attention, and hence have the strongest database supporting the use of fluvoxamine in their treatment. Looking at these studies in their totality and at the available postmarketing surveillance data, one can conclude that at the commonly used doses of 50–300 mg/day, fluvoxamine is well tolerated and shares the superior side-effect and safety profile of the SSRIs as compared with tricyclic antidepressants. However, fluvoxamine's pharmacodynamic and pharmacokinetic properties, including its inhibitory effects on some CYP enzymes, help differentiate it from other SSRIs.

Compared with other SSRIs, fluvoxamine is relatively selective for the serotonin transporter, and it is less protein-bound than fluoxetine, paroxetine, or sertraline. Adverse events from drug–drug

interactions with fluvoxamine are rare, but caution should be exercised when combining fluvoxamine, a potent inhibitor of CYP1A2, with substrates of this isozyme, including theophylline, clozapine, and (to a lesser degree) carbamazepine. Through inhibition of CYP2C19 and CYP3A4, fluvoxamine could also interact with substrates of these isozymes, including coumadin, terfenadine, astemizole, alprazolam, and diazepam.

Fluvoxamine's relatively short half-life makes twice-daily dosing preferable but does not seem to lead to a significant discontinuation syndrome on abrupt discontinuation. A controlled-release formulation that can be dosed once daily has been investigated in OCD and social anxiety clinical trials, with positive efficacy and tolerability reported (Davidson et al. 2004; Hollander et al. 2003; D. J. Stein et al. 2003; Westenberg et al. 2004). This formulation became available in the United States in 2008.

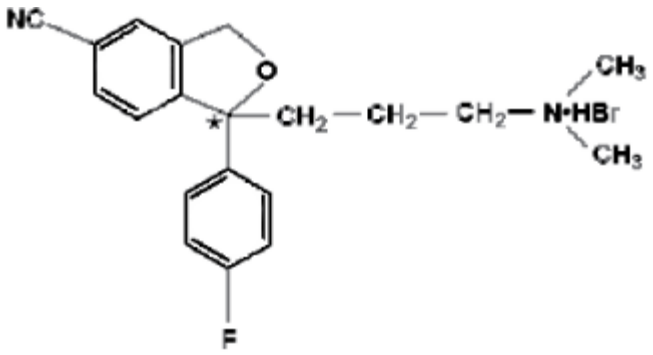
Chapter 17. Citalopram and *S*-Citalopram

CITALOPRAM AND *S*-CITALOPRAM: INTRODUCTION

Citalopram (Celexa) and its pharmacologically active enantiomer, *S*-citalopram (Lexapro), are among the most selective serotonin (5-HT) reuptake inhibitors available. Both drugs are widely prescribed and have been shown in large-scale controlled trials to be effective in the treatment of depression; *S*-citalopram has also been shown in large-scale controlled trials to be effective in the treatment of anxiety disorders. In addition, both drugs are well tolerated in patients and show a low potential for pharmacokinetic drug interactions. Citalopram and *S*-citalopram have similar efficacy in the treatment of depression, with some studies suggesting a modest superiority of *S*-citalopram over citalopram in some measures of efficacy, including a possibly faster onset of therapeutic effect for *S*-citalopram. Antagonism of the effects of *S*-citalopram by *R*-citalopram has been invoked to explain the purported therapeutic differences between the two drugs. In addition, the affinity of citalopram for histamine receptors appears to reside in the *R*-enantiomer, suggesting that *S*-citalopram has a decreased potential for antihistaminergic side effects. Whether the postulated superiority of *S*-citalopram over citalopram is clinically meaningful in psychiatric practice requires further study.

HISTORY AND DISCOVERY



Citalopram (Lu 10-171), 1-(3-[dimethylamino]propyl)-1-(*p*-fluorophenyl)-5-phthalancarbonitrile, is a bicyclic phthalane derivative (molecular weight = 405.35 Da) with a chemical structure that is distinct from other antidepressants. The pharmacology of citalopram was first described in 1977 (Christensen et al. 1977; Hyttel 1977b). Citalopram was discovered in a series of ring system substitutions of phthalane derivatives and was shown to be a very potent inhibitor of 5-HT reuptake in both in vitro and in vivo models (Hyttel 1977b, 1978). In contrast, it was not active in models of norepinephrine (NE) reuptake, and it inhibited dopamine (DA) reuptake only at extremely high concentrations. In addition, it did not affect the activity of monoamine oxidase (MAO) (Hyttel 1977b). It was subsequently discovered that all of the inhibitory activity of citalopram on 5-HT reuptake resides in the *S*-(+)-enantiomer (*S*-citalopram) (Hyttel et al. 1992). Originally introduced in Denmark in 1989, citalopram was approved by the U.S. Food and Drug Administration (FDA) for the treatment of depression in July 1998. *S*-citalopram received FDA approval for the treatment of major depressive disorder in August 2002 and for the treatment of generalized anxiety disorder (GAD) in December 2003.

STRUCTURE–ACTIVITY RELATIONS

Citalopram has a single chiral center (Figure 17–1). A chiral center is an atom surrounded by an asymmetrical arrangement of atoms such that the three-dimensional configuration is not superimposable on its mirror image. At this chiral center, there are two possible stereoisomers. Often, drugs are produced as a mixture of both stereoisomers; this is referred to as the racemate. However, pharmacological activity or unwanted toxicity may reside in only one of the stereoisomers. Therefore, producing a formulation that contains only one stereoisomer has the potential to improve efficacy and limit toxicity while also extending the period of patent protection for the compound. Increasingly, drug companies are performing "chiral switches" and converting the formulation of a drug from the racemate to one pure enantiomer (Agranat et al. 2002). This is the case with citalopram, which was

originally characterized and marketed as the racemate, but subsequently the single stereoisomer of citalopram, *S*-citalopram, has been developed for the treatment of depression and other psychiatric disorders.

Preclinical studies indicate that inhibition of 5-HT transporter activity resides in the *S*-enantiomer (Hyttel et al. 1992), with *S*-citalopram being 30-fold more potent than *R*-citalopram at inhibiting 5-HT transport (Owens et al. 2001). Molecular modeling has suggested that the lower potency of *R*-citalopram may be due to steric hindrance associated with the interaction of *R*-citalopram with the primary binding site on the 5-HT transporter (Ravna et al. 2003). *S*-citalopram also appears to be more selective than *R*-citalopram both in terms of inhibition of monoamine reuptake and in terms of neurotransmitter receptor interactions (Owens et al. 2001). Additionally, there is some in vitro evidence that *S*-citalopram has a slightly lower potential to interact with the liver cytochrome P450 (CYP) system compared with *R*-citalopram, thus decreasing the likelihood of drug–drug interactions at the level of drug metabolism (von Moltke et al. 2001).

A possible explanation for the postulated modest superiority of *S*-citalopram over citalopram in some measures of antidepressant efficacy is provided by the evidence that the *R*-enantiomer of citalopram may interfere with the activity of the *S*-enantiomer (Sanchez 2006). The ability of *R*-citalopram to antagonize the effects of *S*-citalopram has been obtained from a variety of behavioral (Fish et al. 2004; Sanchez and Kreilgaard 2004; Sanchez et al. 2003b, 2003c) and physiological (El Mansari et al. 2005, 2007; Mork et al. 2003) assays. This antagonism has been hypothesized to result from a kinetic interaction at the level of the 5-HT transporter (Storustovu et al. 2004).

PHARMACOLOGICAL PROFILE

Citalopram

Citalopram is one of the most selective of the selective 5 HT reuptake inhibitors (SSRIs) approved to date, with a 524-fold lower potency for inhibiting the human NE transporter and a >10,000-fold lower potency for inhibiting the human DA transporter (Owens et al. 2001). In addition, citalopram has low affinity for a wide variety of neurotransmitter receptors, including dopamine$_1$ (D_1) and dopamine$_2$ (D_2); serotonin$_{1A}$ (5-HT_{1A}), serotonin$_{2A}$ (5-HT_{2A}), and serotonin$_{2C}$ (5-HT_{2C}); α_1-, α_2-, and β-adrenergic; muscarinic cholinergic (Hall et al. 1984; Hyttel 1982, 1994; Hyttel and Larsen 1985; Richelson and Nelson 1984); and γ-aminobutyric acid (GABA) and opiate receptors (Hyttel et al. 1995). Citalopram has been reported to have submicromolar affinity for the histamine$_1$ (H_1) receptor (Hyttel 1994; Richelson and Nelson 1984), but recent evidence indicates that this is true only for the

R-enantiomer (Owens et al. 2001). Citalopram does not show significant inhibition of MAO (Hyttel 1977b).

Behavioral studies have shown citalopram to be a potent and selective inhibitor of 5-HT reuptake. In mice, citalopram is potent at potentiating the L-5-hydroxytryptophan (L-5-HTP) or tryptophan-induced 5-HT syndrome (Christensen et al. 1977; Hyttel 1994). In rats, citalopram decreases spontaneous tail flicks that are induced by *p*-chloroamphetamine, which acts by entering 5-HT neurons through the 5-HT transporter. In contrast, citalopram is ineffective in models that reflect in vivo inhibition of DA and NE reuptake (Hyttel 1994).

Citalopram is active in various behavioral models related to antidepressant activity. For example, in rats citalopram reverses helpless behavior in the learned helplessness paradigm (Martin et al. 1990), and it reverses the effects of chronic mild stress-induced decreases in sucrose consumption (Papp et al. 2002; Przegalinski et al. 1995). In mice, citalopram reverses the immobility induced by forced swimming in a confined space (Sanchez and Meier 1997). Citalopram also has antiaggressive activity in animal models, as shown by a decrease in isolation-induced aggressive behavior in male mice that have been pretreated with the 5-HT precursor L-5-HTP (Sanchez and Hyttel 1994). Citalopram is also active in various behavioral models designed to predict anxiolytic activity. For example, in rats, citalopram antagonizes freezing behavior produced by conditioned fear (Inoue 1993), and in both rats and mice, citalopram increases exploratory behavior in a black-and-white approach–avoidance test box (Sanchez 1995).

Similar to other SSRIs, citalopram potentiates the effects of some pharmacological agents. For example, the anticonvulsant activity of diphenylhydantoin administered prior to electroshock-induced convulsions in mice (Hyttel et al. 1995) and the antinociceptive effects of opiates administered prior to the hot plate test in rats are potentiated (Larsen and Hyttel 1985; Sugrue 1979).

S-Citalopram

S-citalopram is also a highly potent inhibitor of 5-HT reuptake, with a K_i for binding to the human 5-HT transporter of 1.1 nM compared with a K_i of 1.9 nM for citalopram and 36 nM for *R*-citalopram (Owens et al. 2001). *S*-citalopram is the most selective SSRI approved for clinical use, with a 2,600-fold lower potency for inhibiting the human NE transporter and a >45,000-fold lower potency for inhibiting the human DA transporter. *S*-citalopram also has no appreciable binding affinity for a large number of other neurotransmitter receptors including all those mentioned above in relation to the selectivity of citalopram (Owens et al. 2001; Sanchez et al. 2003a). *S*-citalopram displays a weak affinity (K_i = 100 nM) for binding to the σ_1 receptor, with both citalopram and *R*-citalopram displaying a similar affinity. Finally, there is a low level of binding affinity (K_i = 181 nM) displayed by *R*-citalopram for the histamine H_1 receptor (Owens et al. 2001), which could explain any antihistaminergic side effects that may be associated with citalopram.

S-citalopram also has potent activity in various in vivo paradigms (for a review, see Sanchez et al. 2003a). For example, in an in vivo model of 5-HT reuptake inhibition, *S*-citalopram potentiates the L-5-HTP-induced 5-HT syndrome. *S*-citalopram is also active in behavioral models of antidepressant, antiaggressive, and anxiolytic activity. In mice, *S*-citalopram reverses the immobility induced by forced swimming. *S*-citalopram is also potent at inhibiting aggressive behavior in male mice following pretreatment with L-5-HTP. Finally, *S*-citalopram has anxiolytic-like activity, as shown in mice by an increase in exploratory activity in the black-and-white approach–avoidance test box and in rats by inhibition of ultrasonic vocalization induced by foot shock. In these in vivo paradigms, the potency of *S*-citalopram ranges from similar to citalopram to approximately twofold greater than citalopram. In contrast, in the majority of these paradigms *R*-citalopram is severalfold less potent than either *S*-citalopram or citalopram.

PHARMACOKINETICS AND DISPOSITION

Citalopram

Citalopram is well absorbed after oral administration, with an absolute bioavailability for citalopram tablets of 80% compared with intravenous administration (Joffe et al. 1998). The peak plasma concentration is normally observed 2–4 hours following an oral dose (Kragh-Sorensen et al. 1981). The bioavailability of citalopram is not affected by food (Baumann and Larsen 1995), and it is subject to very little first-pass metabolism (Kragh-Sorensen et al. 1981). The apparent volume of distribution is 12–16 L/kg (Kragh-Sorensen et al. 1981; Overo 1982), which indicates that the drug distributes widely. There is a linear relationship between steady-state plasma concentration and dose (Bjerkenstedt et al. 1985), and plasma protein binding is approximately 80% (Baumann and Larsen 1995). Because citalopram is less strongly protein bound than many other compounds, it is less susceptible to drug–drug interactions at the level of protein binding. Systemic clearance of citalopram was determined to be 0.3–0.4 L/minute in a study of healthy volunteers given a single intravenous dose. This value indicates a low hepatic extraction ratio (Baumann and Larsen 1995). In a separate study, the renal clearance of citalopram was determined to be approximately 0.05–0.08 L/minute (Sindrup et al. 1993).

Racemic citalopram undergoes *N*-demethylation by the hepatic P450 system to the major metabolite, monodesmethylcitalopram (DCT). In vitro studies using human liver microsomes and heterologously expressed individual human cytochromes indicate that CYP2C19, CYP3A4, and CYP2D6 all contribute approximately equally to the formation of DCT (Kobayashi et al. 1997; Rochat et al. 1997; von Moltke et al. 1999). DCT also undergoes N-demethylation to the minor metabolite didesmethylcitalopram (DDCT) by the actions of CYP2D6 (Sindrup et al. 1993; von Moltke et al. 2001). Compared with citalopram, DCT is 4 times less potent than an SSRI and 11 times more potent than an NE reuptake inhibitor (Hyttel 1982). Because DCT only weakly crosses the blood–brain barrier and usually is present at significantly lower concentrations than citalopram, the contribution of DCT to the antidepressant efficacy of citalopram is likely negligible (van Harten 1993). Clinical studies indicate that the half-lives for citalopram, DCT, and DDCT are approximately 36 hours, 50 hours, and 100 hours, respectively (Dalgaard and Larsen 1999; Kragh-Sorensen et al. 1981; Overo 1982). In a study in which a single radioactive dose of citalopram was administered to volunteers, 75% of the radioactivity was recovered in the urine and 10% in the feces. The radioactivity in the urine corresponded to citalopram (26%), DCT (19%), and DDCT (9%) (Dalgaard and Larsen 1999). The remainder was composed of the *N*-oxide derivative of citalopram (7%) and the glucuronide conjugates of citalopram (14%), DDCT (6%), and citalopram acid (12%).

The potential for drug–drug interactions at the level of inhibition of liver metabolism is low for both citalopram and *S*-citalopram (see below). In vitro studies show that citalopram only weakly inhibits CYP1A2 and CYP2C19 and does not significantly inhibit CYP2C9, CYP2E1, and CYP3A (von Moltke et al. 1999). Citalopram is a relatively weak inhibitor of CYP2D6.

Because citalopram is metabolized by human cytochromes that display genetic polymorphisms, it is possible that metabolism of citalopram may display genetic variability. In a study of 69 depressed patients who were phenotyped as extensive and poor metabolizers of the CYP2C19 pathway (mephenytoin), poor metabolizers had significantly higher ratios of citalopram to DCT compared with extensive metabolizers, indicating that the metabolism of citalopram is impaired in poor metabolizers (Baumann et al. 1996). Similar results were seen in two separate studies involving 24 healthy male volunteers and 77 healthy Chinese volunteers in which steady-state plasma concentrations of citalopram were elevated in poor metabolizers of the CYP2C19 pathway (Sindrup et al. 1993; Yu et al. 2003). Additionally, both of these studies showed that the further metabolism of DCT to DDCT was impaired in poor metabolizers of the CYP2D6 pathway (Baumann et al. 1996; Sindrup et al. 1993). Taken together, these data provide evidence for the roles of CYP2C19 and CYP2D6 in the metabolism of citalopram.

The effects of age and physiological status on the metabolism of citalopram have also been studied. In elderly patients (Overo et al. 1985; Uehlinger et al. 1995) and patients with liver disease (Joffe et al. 1998), the clearance of citalopram is decreased, and a decrease in dosage may be necessary for these patients. In a study of seven patients, renal insufficiency did not have a significant effect on the plasma concentration of citalopram (Joffe et al. 1998). Therefore, reduced renal function does not have a major impact on the kinetics of citalopram, and dosage adjustment may not be necessary. It should be noted that the data for the effects of renal insufficiency were following a single dose. No published studies have yet reported the effects of impaired kidney function in chronic treatment of patients with citalopram.

S-Citalopram

The clinical pharmacokinetic characteristics of *S*-citalopram have recently been reviewed and are similar to those described for citalopram (N. Rao 2007). The pharmacokinetic characteristics of *S*-citalopram are essentially the same regardless of whether patients are given a single oral dose of 20 mg of *S*-citalopram or 40 mg of racemic citalopram (which contains 20 mg of *S*-citalopram). This indicates that there is no pharmacokinetic interaction or interconversion between *R*-citalopram and *S*-citalopram (N. Rao 2007; Sogaard et al. 2005). The human cytochromes involved in the metabolism of *S*-citalopram and its metabolite *S*-DCT are the same as those reported for racemic citalopram (von Moltke et al. 2001). The average half-lives of the two enantiomers differ. In one study of five hospitalized depressed patients, the half-life of *S*-citalopram (42 ± 13 h) was shorter than that of the *R*-enantiomer (*R*-citalopram; 66 ± 11 h). Likewise, the half-life of the major metabolite *S*-DCT (93 ± 35 h) was significantly shorter than that of *R*-DCT (228 ± 148 h) (Voirol et al. 1999). The shorter reported half-life for *S*-citalopram is consistent with the trend toward lower steady-state plasma concentrations of *S*-citalopram and *S*-DCT compared with *R*-citalopram and *R*-DCT in patients (Bondolfi et al. 1996; Foglia et al. 1997; Sidhu et al. 1997).

Both *S*-citalopram and *R*-citalopram and their metabolites show weak or negligible inhibition in vitro of the various liver P450 enzymes (von Moltke et al. 2001). In a clinical study, *S*-citalopram did show some inhibition of CYP2D6, measured as a change in the pharmacokinetics of the CYP2D6 substrate metoprolol, but to a significantly lesser extent compared with paroxetine or fluoxetine (Preskorn et al. 2007). It should be noted that both *R*-DDCT and *S*-DDCT show moderate potency for inhibiting CYP2C19, but this is unlikely to be clinically relevant since the median inhibitory concentration (IC_{50}) values for CYP2C19 are more than two orders of magnitude above the low plasma concentrations achieved for these two metabolites (Baumann and Larsen 1995). The only substantial inhibition of CYP2D6 that has been noted in vitro results from *R*-DCT (IC_{50} = 25.5 μM), which is still an order of magnitude less potent than paroxetine (IC_{50} = 2.6 μM) (von Moltke et al. 2001). However, this inhibitory activity of the metabolite of *R*-citalopram suggests a lower potential for *S*-citalopram to inhibit liver P450 enzymes compared with racemic citalopram.

MECHANISM OF ACTION

The majority of studies on mechanism of action have focused on citalopram, with a relatively limited number of studies using *S*-citalopram. Because the antidepressant activity of citalopram results from *S*-citalopram, the majority of the conclusions from these studies pertain to both citalopram and *S*-citalopram. Studies that specifically utilized *S*-citalopram are reviewed in the *S*-citalopram section that immediately follows.

Citalopram

Citalopram is a potent and selective inhibitor of 5-HT reuptake and acts by binding directly to the 5-HT transporter. In vitro studies demonstrate that citalopram blocks 5-HT reuptake by rabbit thrombocytes (Hyttel 1977b), rat brain synaptosomes (Hyttel 1978, 1982; Richelson and Pfenning 1984; Vaatstra et al. 1981; Waldmeier et al. 1979), rat brain slices (Classen et al. 1984; Dyck 1984; Galzin et al. 1985),

and rat lung slices (Drew and Siddik 1980). Blockade of 5-HT reuptake is of the competitive type, as shown in thrombocytes and synaptosomes, and the accumulation of 5-HT is not due to citalopram-induced 5-HT release (Hyttel 1977b, 1978). This is consistent with experiments demonstrating that citalopram does not alter spontaneous release of endogenous or preloaded 5-HT from rat cortical slices, but it does increase the electrically induced release of 5-HT (Baumann and Waldmeier 1981). The IC_{50} values for 5-HT reuptake in rat brain synaptosomes are 3.9 nM (citalopram), 2.1 nM (*S*-citalopram), and 275 nM (*R*-citalopram) (Sanchez and Brennum 2000).

Citalopram is one of the most selective inhibitors of radioligand binding to the 5-HT transporter versus the NE transporter. The K_i for inhibiting [^{3}H]citalopram binding to rat cortical membranes was 0.75 nM, compared with 3,042 nM for inhibiting [^{3}H]nisoxetine binding. A similar selectivity was found for inhibiting the binding of the same radioligands to the cloned human 5-HT and NE transporters expressed in transfected cells. In addition, the K_is for inhibiting [^{3}H]5-HT and [^{3}H]NE reuptake into these transfected cells were 8.9 nM and 30,285 nM, respectively (Owens et al. 1997). Citalopram appears to bind at or near the site that 5-HT occupies during transport (Barker et al. 1998).

Citalopram, at doses that profoundly affect 5-HT reuptake, does not alter the endogenous levels of 5-HT, NE, or DA in the rat brain (Hyttel 1977b). Inhibition of 5-HT reuptake should result in an increase in synaptic levels of 5-HT, resulting in decreased 5-HT neuronal firing via feedback inhibition. This inhibition should decrease 5-HT synthesis and turnover, and this effect has been observed following administration of citalopram to rats (Hyttel 1977a).

As with other SSRIs, acute administration of citalopram to rats increases extracellular 5-HT in the raphe nucleus (Invernizzi et al. 1992). Acute citalopram also potently inhibits the firing of 5-HT neurons in the dorsal raphe nucleus (DRN), presumably through activation of 5-HT_{1A} autoreceptors (Arborelius et al. 1995; Chaput et al. 1986). The inhibition of 5-HT neurons in the raphe nucleus is thought to limit the ability of a single administration of SSRIs to increase extracellular 5-HT in frontal brain regions that receive projections from the raphe nucleus. As expected, coadministration of 5-HT autoreceptor antagonists blocks the ability of acute citalopram to inhibit firing of DRN neurons (Arborelius et al. 1995) and increases the ability of citalopram to elevate extracellular 5-HT levels in various forebrain regions (Hjorth 1993; Hjorth et al. 1996; Invernizzi et al. 1997). This acute effect of citalopram on 5-HT neurons in the DRN is also seen in mice, but not in knockout mice, where the target for the actions of citalopram, the 5-HT transporter, has been eliminated (la Cour et al. 2001).

Some studies of the interaction between antidepressants and the 5-HT transporter indicate that in addition to the primary high-affinity binding site, there is also a second low-affinity allosteric site. The high-affinity site is responsible for inhibition of 5-HT transport, whereas the allosteric site modulates the dissociation rate of ligand binding at the high-affinity site (Neubauer et al. 2006; Plenge et al. 1991). When citalopram binds to the allosteric site, it is thought to inhibit the dissociation of citalopram from the primary binding site, thereby enhancing the inhibition of 5-HT transport (Plenge and Mellerup 1997). Interestingly, both enantiomers of citalopram bind to this site to inhibit dissociation of citalopram with *S*-citalopram being three to five times more potent than *R*-citalopram at binding to this allosteric site (Chen et al. 2005).

Because antidepressants usually require weeks of administration to be therapeutically beneficial, several studies have described how repeated dosing alters the effects of citalopram on serotonergic neuronal function. Much as with other SSRIs, the ability of citalopram to inhibit the firing of 5-HT neurons in the DRN is greatly reduced after 14 days of repeated administration (Chaput et al. 1986). This is associated with an increase in the ability of citalopram to elevate the extracellular levels of 5-HT in the cortex (Invernizzi et al. 1994). These two effects appear to result from a desensitization of 5-HT_{1A} autoreceptors because repeated citalopram administration decreases the effectiveness of 5-HT_{1A} agonists to inhibit firing of 5-HT neurons in the DRN (Chaput et al. 1986) and to decrease

extracellular 5-HT levels in the rat forebrain (Cremers et al. 2000; Invernizzi et al. 1994). It should be noted, however, that one study failed to demonstrate a chronic citalopram-induced desensitization of 5-HT_{1A} autoreceptors (Hjorth and Auerbach 1994). This adaptive change of 5-HT_{1A} receptors following repeated administration of citalopram, as well as other SSRIs, has been postulated to underlie the slow onset of antidepressant efficacy that is observed clinically (Blier and de Montigny 1994).

Evidence suggests that a variety of antidepressants, including those that block monoamine reuptake or metabolism, produce their therapeutic response in part by overcoming depression-associated decreases in neurogenesis and synaptogenesis. Brain-derived neurotrophic factor (BDNF), which supports neuroplasticity, has been implicated in both the pathophysiology of depression and the therapeutic response to antidepressants. Citalopram has been shown to affect BDNF expression and signaling through the primary BDNF receptor, TrkB. In terms of BDNF expression, citalopram increases the levels of BDNF mRNA in various subregions of the ventral hippocampus either alone or in combination with exercise (wheel running) in rats (Russo-Neustadt et al. 2004). Citalopram, like several other antidepressants, also induces signaling through TrkB. Acute injection of citalopram into rats results in a significant increase in the autophosphorylation of TrkB within the rat anterior cingulate and dentate gyrus within 60 minutes (Rantamaki et al. 2007). Acute citalopram treatment was also associated with activation of TrkB-associated phospholipase Cγ1 and an increase in the phosphorylation of the transcription factor cAMP response element–binding protein (CREB). The relevance of these findings is shown by the abolishment of the effects of citalopram in the forced-swim test in transgenic mice lacking functional TrkB receptors (Rantamaki et al. 2007). Finally, there are preliminary clinical data suggesting that a polymorphism within the coding region for BDNF (Val66Met) is associated with the therapeutic response to citalopram. In Korean patients with major depressive disorder, responders to 8 weeks of citalopram treatment were more likely to have the Met allele (Val/Met or Met/Met) (78.9%) compared with nonresponders (46.2%) (Choi et al. 2006).

A number of studies have implicated the 5-HT_{2A} receptor in a variety of neuropsychiatric disorders (Norton and Owen 2005), and there is evidence implicating the 5-HT_{2A} receptor in the mechanism of action of antidepressants. For example, preclinical studies show that a number of antidepressant treatments, including citalopram administration, downregulate brain 5-HT_{2A} receptors in a time frame that corresponds to the onset of therapeutic effect in humans (Chen and Lawrence 2003; Peremans et al. 2005; Strome et al. 2005). In addition, antagonism of rodent 5-HT_{2A} receptors blocks the stress-induced reduction in BDNF mRNA (Vaidya et al. 1997). In a large-scale clinical study involving 1,953 patients who participated in the STAR*D trial, a survey of 768 single-nucleotide polymorphisms (SNPs) contained in 68 candidate genes identified a significant association between a polymorphism contained in the second intron of the gene for the 5-HT_{2A} receptor (rs7997012) and treatment response to citalopram. This was observed in the initial discovery sample (n = 859), which consisted of two-thirds of the total number of subjects in the study, and was confirmed in a replication sample (n = 438) consisting of the remaining one-third of the subjects (McMahon et al. 2006). Specifically, those patients who were homozygous for the A allele had an 18% lower risk of treatment failure compared with patients who were homozygous for the G allele. Importantly, this allele was six times more frequent in white compared with black patients, and this was associated with a poorer response to citalopram therapy in the black patient population. While perhaps relevant to clinical work, the functional significance of this intronic polymorphism on the 5-HT_{2A} receptor has yet to be determined.

S-Citalopram

Like citalopram, *S*-citalopram is a potent and highly selective inhibitor of 5-HT reuptake that acts by binding directly to the 5-HT transporter. Acute treatment with *S*-citalopram inhibits the firing of 5-HT neurons in the DRN presumably through 5-HT-dependent activation of 5-HT_{1A} autoreceptors (Sanchez et al. 2003a). Additionally, the adaptive changes in the sensitivity of 5-HT_{1A} autoreceptors that are

postulated to underlie the onset of antidepressant efficacy have also been shown to occur following *S*-citalopram treatment. Specifically, desensitization of 5-HT_{1A} autoreceptors in the rat prefrontal cortex was reported following chronic treatment with *S*-citalopram (Ceglia et al. 2004). Antidepressants have also been postulated to work through changes in neuronal plasticity. *S*-citalopram has been shown to affect cytogenesis within the brain. Cytogenesis refers to the proliferation of new cells that may subsequently differentiate into neurons (neurogenesis). For example, *S*-citalopram treatment for 4 weeks reverses the decrease in cytogenesis that occurs in the subgranular zone of the dentate gyrus in the ventral hippocampus as a result of 2 weeks of chronic mild stress exposure. Importantly, this effect was only seen in a subgroup of rats for which *S*-citalopram reversed chronic mild stress-induced anhedonia; those rats that did not have this behavioral effect did not show the change in cytogenesis (Jayatissa et al. 2006). Because the majority of newly formed cells within the subgranular zone will divide and, if they survive, differentiate into neurons, the authors speculate that the changes in cytogenesis will ultimately affect the number of new neurons that are formed within the granular cell layer of the dentate gyrus.

INDICATIONS AND EFFICACY

Depression

Citalopram

The efficacy of citalopram in the treatment of depression has been shown in at least 11 placebo-controlled clinical trials (for a review, see Keller 2000). In addition to the independently published reports described below, meta-analyses of multiple placebo-controlled studies reported similar findings (Bech and Cialdella 1992; Montgomery et al. 1994). In the United States, three large multicenter clinical trials were conducted. In a 4-week trial, a variable dosage paradigm ranging from 20 mg to 80 mg per day was utilized among 180 patients with depression or melancholia. At the end of the study, patients on citalopram showed a significant improvement on the Hamilton Rating Scale for Depression (Ham-D), the Clinical Global Impressions (CGI) Scale, and the Zung Self-Rating Depression Scale compared with placebo. The improvement in the Ham-D score was seen as early as 1 week (Mendels et al. 1999).

In a second trial, patients (n = 650) with moderate to severe depression were assigned a fixed dosage of 10, 20, 40, or 60 mg of citalopram or placebo for 6 weeks (Feighner and Overo 1999). Citalopram was significantly more efficacious than placebo (P <0.05) based on reductions in the Ham-D and Montgomery-Åsberg Depression Rating Scale (MADRS) scores, and the CGI–Improvement (CGI-I) and CGI–Severity of Illness (CGI-S) ratings. All four doses of citalopram significantly improved the Ham-D score (P <0.01), and the response rate with all four doses was significantly greater than with placebo.

A third placebo-controlled study compared the efficacy of citalopram (20–60 mg/day) with that of another SSRI, sertraline (50–150 mg/day), in 323 patients with DSM-IV (American Psychiatric Association 1994)–defined major depression. Both treatments produced significantly greater improvement than placebo in the Ham-D score (P <0.05), the MADRS score (P <0.01), the CGI-S rating (P <0.05), and the CGI-I rating (P <0.05) (Stahl 2000).

Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial

The effectiveness of citalopram has also been demonstrated in a study designed to simulate real-world conditions for the treatment of depression. Treatment with citalopram was used in the first phase of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial. This large-scale multicenter study enrolled 4,041 patients with nonpsychotic major depression from 23 psychiatric and 18 primary care settings across the United States in a test of various antidepressant therapies (Rush et al. 2004). The first phase of the study consisted of 12 weeks of treatment with a flexible dosage of citalopram initiated at 20 mg/day and gradually increased on an individualized basis to 60 mg/day,

and the primary outcome measure was depression remission defined as a score of ≤7 on the 17-item Ham-D (Ham-D_{17}) or a score of ≤5 on the 16-item Quick Inventory of Depressive Symptomatology, Self-Report (QIDS-SR). Response rates were defined as ≥50% reduction in the QIDS-SR score. Approximately 80% of the 2,876 patients who were included in an analysis of the first phase of the study had chronic or recurrent major depression, with most of these patients having a variety of other comorbid general medical and psychiatric conditions. The mean daily dose of citalopram at study exit was 41.8 mg, the remission rates were 28% (Ham-D) and 33% (QIDS-SR), and the response rate was 47% (QIDS-SR) (Trivedi et al. 2006). These response and remission rates are comparable to those found in controlled 8-week clinical trials examining the efficacy of acute antidepressant treatment.

Long-term treatment with citalopram

Early discontinuation of antidepressant treatment is associated with depression relapse. To prevent relapse, it is recommended that antidepressant treatment should be continued for at least 4–6 months (Montgomery 1996). Two placebo-controlled studies indicate that for patients with an acute therapeutic response to citalopram, continuation of citalopram therapy at the same dose (20, 40, or 60 mg/day) for 24 additional weeks significantly decreases the relapse rate compared with placebo (Montgomery et al. 1993; P. Robert and Montgomery 1995). These studies suggest that citalopram may be effective in continuation therapy to prevent depression relapse. Depression also tends to be a recurrent illness, and many patients experience multiple episodes within a lifetime. Two studies have shown that long-term (at least 48 weeks) administration of citalopram at the same fixed dose at which patients initially showed therapeutic response (20–60 mg/day) can significantly increase the time before depression recurs in adult patients (18–65 years) and in the elderly (≥65 years) (Hochstrasser et al. 2001; Klysner et al. 2002). These studies suggest that long-term administration of citalopram may be beneficial in patients who have a history of recurrent depression.

S-Citalopram

A number of placebo-controlled clinical trials and retrospective analyses have demonstrated the efficacy of *S*-citalopram in the treatment of major depression. In addition, several clinical studies have directly compared *S*-citalopram to citalopram and a variety of other antidepressants. In general, *S*-citalopram was at least as effective as other widely used antidepressants, and in some clinical trials it has been suggested to be superior to other antidepressants based on modestly greater changes in various depression rating scales, especially in severely depressed patients. In addition, also based on depression rating scales, *S*-citalopram has been suggested in a few clinical trials to possibly have a faster onset of therapeutic effect occurring as early as 1 week. The details of these studies are reviewed below. Whether the modest differences between *S*-citalopram and other antidepressants in controlled clinical trials translate into a therapeutically meaningful difference in the treatment of depression in psychiatric practice remains to be demonstrated.

Three placebo-controlled clinical trials have demonstrated the efficacy of *S*-citalopram in treatment of depression. Results of a double-blind, placebo-controlled, fixed-dose multicenter clinical trial (n = 491) revealed that *S*-citalopram produced significant improvement compared with placebo at both doses tested (10 mg/day or 20 mg/day) (Burke et al. 2002). Significant improvement was seen within 1 week, and *S*-citalopram at 10 mg/day was at least as effective as citalopram at 40 mg/day in improving depressive symptomatology by the end of the 8-week study. Similar results were seen in another study in which patients receiving 10 mg/day of *S*-citalopram (n = 191) showed significant improvement compared with placebo (n = 189) by the end of the 8-week study (Wade et al. 2002).

In a separate double-blind study, citalopram (20–40 mg/day; n = 160) and *S*-citalopram (10–20 mg/day; n = 155) were compared with placebo (n = 154) in the treatment of primary care patients with major depression (MADRS scores ≥22 and ≤40) (Lepola et al. 2003; Montgomery et al. 2001b). Treatment with *S*-citalopram resulted in significantly greater improvement compared with placebo

after 1 week. This difference was maintained through week 8, and the adjusted mean change in MADRS score was 2.9 points ($P = 0.002$). Treatment with *S*-citalopram also produced a significantly greater improvement compared with placebo on the CGI-I and CGI-S subscales from week 1 onward. In contrast, treatment with citalopram demonstrated superiority to placebo only at week 8 and only on the CGI-I scale. At the end of the study, significantly more patients had responded (defined as ≥50% decrease in MADRS total score) to *S*-citalopram (63.7%) than to either citalopram (52.6%; $P = 0.021$) or placebo (48.2%; $P = 0.009$).

Comparison of *S*-citalopram with citalopram

Two clinical trials that did not include a placebo control have compared *S*-citalopram to citalopram. In a 24-week double-blind, fixed-dosage study, *S*-citalopram at 10 mg/day ($n = 195$) was compared with citalopram at 20 mg/day ($n = 182$) in a primary care setting (Colonna et al. 2005). In this study, *S*-citalopram was as effective as citalopram as assessed by a decrease in the total MADRS score using a repeated-measures analysis of covariance (ANCOVA) to assess treatment response at all time points. Based on the mean change from baseline in the CGI-S score, *S*-citalopram was superior to citalopram by week 24. Interestingly, exploratory analysis revealed a statistically significant greater response to *S*-citalopram over citalopram in moderately depressed subjects (MADRS score ≥22 and <30) in the change in MADRS score and CGI-S score from baseline at both 8 and 24 weeks. Finally, the effectiveness of long-term treatment was evidenced by the observation that more than half of the patients (55% and 51% for *S*-citalopram and citalopram, respectively) who had not responded by week 8 were in remission by week 24. In a second study, *S*-citalopram at 20 mg/day ($N = 138$) was compared with citalopram at 40 mg/day ($n = 142$) in the outpatient treatment of major depressive disorder (Moore et al. 2005). The mean change in total MADRS score was greater in the *S*-citalopram group (−22.4 ± 12.9) than in the citalopram group (−20.3 ± 12.7; $P < 0.05$). In addition, there were more treatment responders (defined as a decrease from initial MADRS score of ≥50%) in the *S*-citalopram group (76.1%) than in the citalopram group (56.1%; $P < 0.01$).

Finally, three pooled analyses suggest that *S*-citalopram has a faster onset of clinical effect when compared with citalopram (Gorman et al. 2002; Kasper et al. 2006; Lepola et al. 2004). In these studies, a significantly greater therapeutic response compared with placebo was achieved within 1 week for *S*-citalopram (10–20 mg/day), whereas citalopram (20–40 mg/day) required approximately 4 weeks of treatment. Whether this study observation results in a clinically meaningful faster onset of therapeutic effect requires further analysis.

Comparison of *S*-citalopram with other antidepressants

The antidepressant efficacy of *S*-citalopram has been compared with that of several other commonly used SSRIs. Two published long-term randomized, double-blind studies directly compared *S*-citalopram with paroxetine. In a flexible-dosage study, *S*-citalopram at 10–20 mg/day was compared with paroxetine at 20–40 mg/day, and in a fixed dosage study *S*-citalopram at 20 mg/day was compared with paroxetine at 40 mg/day (Baldwin et al. 2006a; Boulenger et al. 2006). *S*-citalopram was found to be at least as effective as—and, in some measures, possibly modestly superior to—paroxetine in the treatment of severe depression (baseline MADRS total score ≥30). Specifically, in the severely depressed, treatment with 20 mg/day *S*-citalopram ($n = 228$) produced greater improvement than treatment with 40 mg/day paroxetine ($n = 223$). The mean change in total MADRS score at the end of 24 weeks of treatment was −25.2 points with *S*-citalopram and −23.1 points with paroxetine ($P < 0.05$), and the percentage of remitters (MADRS ≤12) was 75% with *S*-citalopram and 67% with paroxetine ($P < 0.05$) (Boulenger et al. 2006). In addition, *S*-citalopram (10–20 mg/day) compared with paroxetine (20–40 mg/day) had fewer adverse events associated with treatment discontinuation (Baldwin et al. 2006a). When compared with sertraline in a randomized, double-blind trial, *S*-citalopram (10 mg/day) was as effective as sertraline (50–200 mg/day) in treating depression, and the two drugs had similar tolerability (Ventura et al. 2007).

Finally, in a randomized, double-blind trial, *S*-citalopram (10 mg/day; *n* = 173) was compared with fluoxetine (20 mg/day; *n* = 164) and placebo (*n* = 180) in the treatment of depression in the elderly (ages 65–93 years) (Kasper et al. 2005a). At the conclusion of the 8-week study, *S*-citalopram was numerically superior to fluoxetine in reducing mean total MADRS score from baseline, although neither drug was statistically superior to placebo.

There are also a large number of retrospective pooled analyses that have compared *S*-citalopram with other SSRIs. In general, these trials provide evidence that *S*-citalopram has a slightly superior efficacy compared with other SSRIs (fluoxetine, sertraline, and paroxetine) based on improvement in ratings on depression scales or percentage of depressed patients experiencing a therapeutic response or remission (Einarson 2004; Kennedy et al. 2006; Llorca et al. 2005).

Several clinical trials have compared *S*-citalopram with the serotonin–norepinephrine reuptake inhibitors (SNRIs) venlafaxine and duloxetine. In two randomized, double-blind trials (Bielski et al. 2004; Montgomery et al. 2004), *S*-citalopram was shown to be as effective as venlafaxine extended-release (XR) in the treatment of major depressive disorder, and *S*-citalopram had significantly better tolerability. One trial was a fixed-dosage study where *S*-citalopram at 20 mg/day was compared with venlafaxine XR at 225 mg/day, and the other was a flexible-dosage study in which *S*-citalopram at 10–20 mg/day was compared with venlafaxine XR at 75–150 mg/day. A retrospective analysis of these two clinical trials (Montgomery and Andersen 2006) suggested that treatment with *S*-citalopram was superior to treatment with venlafaxine XR for patients who were severely depressed (MADRS score ≥30). *S*-citalopram was compared with duloxetine in two randomized, double-blind clinical trials (Nierenberg et al. 2007; Wade et al. 2007). In these two studies, *S*-citalopram had either similar or slightly superior efficacy compared with duloxetine in terms of improvement of depressive symptoms, with *S*-citalopram having a better tolerability profile. Both of these were fixed-dosage studies, with *S*-citalopram at 10 mg/day compared with duloxetine at 60 mg/day in one study (Nierenberg et al. 2007) and *S*-citalopram at 20 mg/day compared with duloxetine at 60 mg/day in the other study (Wade et al. 2007).

Finally, in a retrospective analysis of two randomized, double-blind, placebo-controlled studies (Clayton et al. 2006), *S*-citalopram had a similar antidepressant efficacy compared with bupropion extended-release, while *S*-citalopram interfered with sexual functioning in a significantly greater proportion of patients. In both of these similarly designed flexible-dosage studies, *S*-citalopram at 10–20 mg/day was compared with both bupropion at 300–450 mg/day and placebo.

Long-term treatment with *S*-citalopram

The effectiveness of *S*-citalopram in the prevention of relapse following resolution of a depressive episode was demonstrated in a placebo-controlled clinical trial (Rapaport et al. 2004) in which patients who responded to 8 weeks of open-label treatment with *S*-citalopram (10–20 mg/day) were randomly assigned to receive placebo (*n* = 93) or *S*-citalopram (10–20 mg/day; *n* = 181) for 36 additional weeks. The time to relapse was significantly longer in the *S*-citalopram group compared with the placebo group ($P = 0.013$), and a significantly smaller percentage of patients relapsed in the *S*-citalopram group (26%) compared with the placebo group (40%; $P = 0.01$). The effectiveness of long-term *S*-citalopram therapy in the prevention of recurrence of depression was tested in a group of patients who had been diagnosed with recurrent major depressive disorder (Kornstein et al. 2006). Patients who responded to 16 weeks of open-label treatment with a flexible dosage of *S*-citalopram (10–20 mg/day) were randomly assigned to receive either placebo (*n* = 66) or a fixed dose of *S*-citalopram (10 or 20 mg/day; *n* = 73) for an additional 52 weeks. Time to recurrence was significantly longer in the *S*-citalopram group compared with the placebo group ($P < 0.001$).

S-citalopram treatment of depression with comorbid anxiety disorders

Major depressive disorder with comorbid anxiety has been associated with a poorer prognosis. To

assess the effectiveness of *S*-citalopram in depressed patients with high levels of anxiety, a pooled analysis was performed on three clinical trials that focused on a subpopulation of depressed patients who had baseline inner tension scores (MADRS item 3) of ≥4 (Bandelow et al. 2007). *S*-citalopram (10–20 mg/day; *n* = 131) produced a significantly greater mean change from baseline in the MADRS total score compared with placebo (*n* = 128) at weeks 1, 4, 6, and 8, whereas citalopram (20–40 mg/day; *n* = 132) was not superior to placebo until weeks 6 and 8. In addition, the response to *S*-citalopram exceeded that of citalopram in weeks 1, 6, and 8. Similarly, a prospective open-label trial completed by 649 depressed patients demonstrated that 12 weeks of treatment with *S*-citalopram (10–20 mg/day) was effective in relieving the symptoms of depression regardless of whether the patients had a comorbid anxiety disorder (Olie et al. 2007). These studies indicate that *S*-citalopram is effective in relieving depression in those patients who also experience high levels of anxiety.

Depression in Children and Adolescents

Citalopram

Fluoxetine is currently the only FDA-approved medication for the treatment of depression in children 8 years and older. In addition, the FDA has mandated the placement of black box warnings on product labels to indicate that there is a potential for increased suicidality associated with the use of SSRIs in patients younger than 25 years. Nevertheless, a recent meta-analysis of pediatric trials conducted between 1988 and 2006 indicated that the benefits of antidepressant treatment of the young outweigh the risks (Bridge et al. 2007). Only a limited number of clinical studies have examined the effectiveness of citalopram and *S*-citalopram in the treatment of depression in the young, and the efficacy of these two drugs in this patient group requires further study. Citalopram showed a modest superiority over placebo in the treatment of depression in a double-blind trial involving 174 children and adolescent (ages 7–17 years). The response rate (defined as a score of ≤28 on the Children's Depression Rating Scale–Revised) at week 8 was 36% in patients receiving 20 mg/day citalopram compared with 24% in patients receiving placebo (Wagner et al. 2004). Conversely, citalopram (10–40 mg/day) was not superior to placebo in a clinical trial involving 244 adolescents (ages 13–18 years) receiving treatment for 12 weeks. The percentage of responders and remitters based on the MADRS and the Schedule for Affective Disorders and Schizophrenia for School-Aged Children–Present Episode (Kiddie-SADS-P) scores did not significantly differ between the two groups. Interestingly, there was a significantly better response to citalopram compared with placebo in those patients (approximately one-third of total patients) who were not receiving psychotherapy during the trial (von Knorring et al. 2006). Finally, in an open-label trial conducted in Iran of citalopram (10–40 mg/day) in children and adolescents (ages 8–17 years) with major depressive disorder, 22 out of 24 subjects had a ≥50% decrease in their Ham-D score at the end of 6 weeks of treatment (Shirazi and Alaghband-Rad 2005). While citalopram was effective in this patient sample, the authors noted that 5 of the patients switched to mania during the study. Clearly, additional clinical trials are required to establish the efficacy and safety of citalopram in the treatment of childhood depression.

S-Citalopram

One published clinical trial has examined the effectiveness of *S*-citalopram in the treatment of depression in children and adolescents (Wagner et al. 2006). In this randomized, double-blind trial in adolescents (ages 6–17 years) with major depression, treatment with 10–20 mg/day *S*-citalopram (*n* = 131) was not significantly better than treatment with placebo (*n* = 133).

Posttraumatic Stress Disorder

Citalopram

No large-scale double-blind, placebo-controlled trials have evaluated the effectiveness of citalopram

in the treatment of PTSD. However, a number of small-scale open-label trials with citalopram suggest that it may be effective in the treatment of PTSD in adults (English et al. 2006; Tucker et al. 2004) and adolescents (Seedat et al. 2002).

S-Citalopram

Only one published open-label trial (n = 24) has examined the effectiveness of *S*-citalopram in the treatment of combat veterans with PTSD (S. Robert et al. 2006). At the end of this 12-week study, *S*-citalopram (starting at 10 mg/day and increased to 20 mg/day at week 4) improved symptoms based on a variety of PTSD and depression rating scales, suggesting that it may be an effective treatment for PTSD.

Bipolar Disorder

Citalopram

One pilot study has addressed the effectiveness of citalopram as an adjunctive treatment in bipolar disorder (Schaffer et al. 2006). In this 12-week double-blind trial, 20 patients who were currently being treated with first-line mood stabilizers were randomly assigned to receive flexible dosing of either citalopram (10–50 mg/day) or an additional mood stabilizer, lamotrigine (12.5–200 mg/day). At the end of the study, treatment with either citalopram or lamotrigine produced a similar and statistically significant improvement in depression based on the magnitude of the mean decrease in total MADRS score. In this study, one patient in each of the two treatment groups switched to hypomania, which is consistent with the known risk of antidepressant-induced mood elevation in association with treatment of bipolar disorder (Henry et al. 2001). A large-scale placebo-controlled study is necessary to demonstrate the efficacy of using citalopram for acute treatment of depression in bipolar disorder.

S-Citalopram

To date, no published randomized, controlled trials have examined the effectiveness of *S*-citalopram as an adjuvant therapy for the treatment of bipolar depression. In the only published clinical trial, the effectiveness of *S*-citalopram was examined in a 12-week open-label study of 20 patients with type I or type II bipolar depression (Fonseca et al. 2006). In these patients, the addition of 20 mg/day *S*-citalopram to their mood stabilizer therapy significantly improved their depression as measured by a decrease in the Ham-D total score. It should be noted that 1 patient switched to mania and 2 patients displayed mild symptoms of hypomania. Additional large-scale placebo-controlled trials are necessary to fully evaluate the utility of *S*-citalopram in the treatment of bipolar depression.

Obsessive-Compulsive Disorder

Citalopram

To date, a limited number of clinical studies have evaluated the effectiveness of citalopram in the treatment of obsessive-compulsive disorder (OCD). In the only published large-scale double-blind, placebo-controlled study of citalopram in treatment of OCD (Montgomery et al. 2001a), 401 patients were randomly assigned to receive placebo or a fixed dose of citalopram at 20, 40, or 60 mg/day for 12 weeks. The study was conducted at 53 centers in 12 different countries. All three doses of citalopram were significantly more effective than placebo, as measured on the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) change score. There was no significant difference between the individual doses of citalopram; however, the highest response rate, as determined by a 25% improvement in Y-BOCS score, was 65% for the 60 mg/day group, as compared with 52% and 57.4% for the 40 mg/day and 20 mg/day groups, respectively. The drug was well tolerated, with only 4–6 patients withdrawing from the study in each group due to adverse events. Citalopram appears to be effective

in treating both obsessions and compulsions based on similar results from the Y-BOCS obsessional and compulsive subscores. For both of these subscores, there was a trend for a more rapid onset of effect with higher doses of citalopram. The authors of the study concluded that treatment with citalopram is an effective therapy for OCD and that the higher dose of 60 mg/day may possibly give a better therapeutic response with a more rapid onset. Further analysis of this study was done to identify factors that may predict response to citalopram therapy of OCD. The authors concluded that subjects with a longer history of OCD, more severe OCD symptoms, or previous exposure to SSRIs were less likely to be responders in the citalopram trial (D. J. Stein et al. 2001). This conclusion is similar to that reported for other drugs used in the treatment of OCD.

Three small clinical trials, all lacking placebo control groups, have been published. A 24-week open-label pilot study of 29 patients with OCD showed that 76% of patients receiving 40–60 mg/day of citalopram had decreased symptoms as evaluated by various self- and observer-rated scales such as the Y-BOCS (Koponen et al. 1997). A single blind study (raters were blind, but not patients) with 30 patients compared the efficacy of citalopram (20–60 mg/day; *n* = 11) to fluvoxamine (150–300 mg/day; *n* = 10) and paroxetine (20–60 mg/day; *n* = 9) in a 10-week trial (Mundo et al. 1997). All three groups showed significant improvement, and there was no significant difference in the response for the three groups. The other published study examined the effects of citalopram in children. Twenty-three children (ages 9–18 years) were enrolled in a 10-week open-label design. Citalopram (10–40 mg/day) was beneficial, with 75% of participants showing at least moderate improvement with greater than 20% change in children's Y-BOCS. Only limited conclusions can be drawn from this study due to the possible presence of comorbid illness, the lack of a placebo control, and the fact that all participants received cognitive and behavioral treatment along with the medication (Thomsen 1997). A long-term follow-up to this study revealed that the clinical effectiveness of citalopram (20–70 mg/day) in the long-term therapy of OCD was comparable to that of other SSRIs in children and adolescents and that further improvement can be achieved by extending the treatment period up to 1 year (Thomsen et al. 2001).

S-Citalopram

The effectiveness of *S*-citalopram in the treatment of OCD has been demonstrated in a 24-week multicenter double-blind, placebo-controlled clinical trial (D. J. Stein et al. 2007). In this study patients were randomly assigned to receive placebo (*n* = 115), *S*-citalopram at either 10 mg/day (*n* = 116) or 20 mg/day (*n* = 116), or paroxetine at 40 mg/day (*n* = 119). Based on the primary efficacy measure of a change in Y-BOCS total score from baseline to week 12, *S*-citalopram at 20 mg/day and paroxetine at 40 mg/day produced a significant improvement compared with placebo, and by week 24 all treatments were superior to placebo. The effectiveness of both the 20 mg/day *S*-citalopram and the 40 mg/day paroxetine was evident by week 6. In some of the secondary measures, *S*-citalopram at 20 mg/day was superior to placebo at an earlier time point compared with the reference treatment of paroxetine at 40 mg/day, leading the authors to suggest that *S*-citalopram should be considered a treatment of choice for OCD.

One large-scale study has examined the ability of long-term treatment with *S*-citalopram to prevent relapse of OCD in patients who respond to initial treatment (Fineberg et al. 2007). In the first part of the study, 468 patients enrolled in a 16-week open-label treatment phase with either 10 or 20 mg/day *S*-citalopram. At the end of this phase, 320 patients were defined as responders (Y-BOCS total score decrease by ≥25%) and were entered into the 24-week double-blind relapse prevention phase. Patients were randomly assigned to receive either placebo (*n* = 157) or *S*-citalopram (10 or 20 mg/day; *n* = 163) at the dosage they received during the treatment phase. *S*-citalopram showed superiority over placebo in the primary analysis (time to relapse; $P < 0.001$). A statistically significant greater percentage of patients relapsed in the placebo group (52%) compared with the *S*-citalopram group (23%), as defined by a Y-BOCS total score increase of ≥5 or a lack of efficacy as determined by

the investigator.

Generalized Anxiety Disorder

Citalopram

There are no published large-scale randomized, double-blind clinical trials examining the effectiveness of citalopram in the treatment of GAD. As described in the next section, all large-scale trials have focused on the development of *S*-citalopram for the treatment of GAD. One pilot study examined open-label treatment with citalopram in 13 patients suffering from GAD. In this study citalopram treatment (10–60 mg/day) for 12 weeks produced a significant reduction in GAD symptoms and a marked improvement in social and occupational functioning (Varia and Rauscher 2002).

S-Citalopram

The efficacy of *S*-citalopram in the treatment of GAD has been established is several randomized, controlled clinical trials (Baldwin and Nair 2005). The effectiveness of acute treatment (up to 12 weeks) of GAD has been examined in four clinical trials. Three of these studies had a flexible-dosage, randomized, double-blind, placebo-controlled design and were subjected to pooled analysis (Davidson et al. 2004; Goodman et al. 2005; D. J. Stein et al. 2005). The intent-to-treat population of the pooled study consisted of 840, patients with 421 receiving *S*-citalopram (10–20 mg/day) and 419 receiving placebo. *S*-citalopram was superior to placebo in all three studies based on the change in Hamilton Anxiety Scale (Ham-A) total score from baseline to week 8. A significantly greater fraction of patients receiving *S*-citalopram were responders (47.5%) versus placebo (28.6%), with response defined as a reduction in total Ham-A score of 50% or more. By-visit analyses revealed a significantly greater response for *S*-citalopram compared with placebo by weeks 1 or 2 for all secondary efficacy measures (Goodman et al. 2005). Finally, *S*-citalopram was effective in patients with above-median severity of depressive symptoms at baseline (Ham-D_{17} >12) (D. J. Stein et al. 2005). The fourth study used a fixed-dosage, double-blind design and compared three doses of *S*-citalopram—5 mg/day (n = 134), 10 mg/day (n = 136), and 20 mg/day (n = 133)—with paroxetine 20 mg/day (n = 139) and with placebo (n = 139) (Baldwin et al. 2006b). The primary outcome measure was the adjusted mean change in the Ham-A total score from baseline to week 12. By this measure, both 10 and 20 mg/day *S*-citalopram were superior to placebo, whereas 5 mg/day *S*-citalopram and 20 mg/day paroxetine were not. The last observation carried forward (LOCF) analysis revealed that *S*-citalopram at 10 mg/day was also superior to 20 mg/day paroxetine at week 12. In terms of the time course of the therapeutic response, the separation of active drug from placebo was evident by week 4 onward for 10 and 20 mg/day *S*-citalopram, whereas 20 mg/day paroxetine was superior to placebo only at week 10.

The efficacy of *S*-citalopram in the long-term treatment of GAD has been demonstrated in two controlled clinical trials. In one study, subjects who completed one of the three short-term (8-week) clinical trials described in the preceding paragraph were given the option of entering a 24-week flexible-dosage, open-label study (Davidson et al. 2005). The patients were placed on a dose of 10 mg/day *S*-citalopram, and those patients who had not responded by the end of 4 weeks were given the option of increasing the dosage to 20 mg/day. Of the 526 patients who entered the extension study, 299 (56.8%) completed the 24-week study. Of these, 92% were responders (CGI-I score ≤2) at the end of the study. The average Ham-A score decreased from 13.1 at baseline to 6.9 at the conclusion of the study. In a separate randomized, double-blind, flexible-dosage study, the long-term efficacy of *S*-citalopram (10–20 mg/day; n = 61) was compared with paroxetine (20–50 mg/day; n = 62) over 24 weeks (Bielski et al. 2005). The proportions of patients receiving *S*-citalopram and paroxetine that met the criteria for a satisfactory response (CGI-I ≤2) were 65.0% and 55.7% at week 8 and 78.3% and 62.3% at week 24, respectively. Although a greater percentage of patients

responded to *S*-citalopram, the difference was not statistically significant.

The efficacy of long-term therapy with *S*-citalopram in the prevention of relapse of GAD was evaluated in patients who had initially responded to acute treatment (Allgulander et al. 2006). The initial phase of the study was a 12-week open-label trial of patients with a primary diagnosis of GAD (Ham-A total score ≥20) and used a fixed dose of 20 mg/day *S*-citalopram. Of the 491 patients who participated in this phase, 375 had a satisfactory response (Ham-A total score ≤10) and were randomly assigned to the double-blind relapse prevention phase of the study, in which treatment was continued with either placebo (n = 188) or *S*-citalopram (20 mg/day; n = 187) for an additional 24–76 weeks. A statistically significant smaller proportion of patients relapsed (increase in Ham-A total score of ≥15 or a lack of efficacy as judged by the investigator) in the *S*-citalopram group (19%) compared with the placebo group (56%). *S*-citalopram was well tolerated, with 8% of patients withdrawing due to adverse events compared with 7% of placebo-treated patients.

Panic Disorder

Citalopram

Few well-controlled studies have evaluated the effectiveness of citalopram in the treatment of panic disorder. In a 1-year placebo-controlled, double-blind study, 475 patients were assigned to either placebo or one of three fixed dosage ranges of citalopram (10 or 15 mg/day, 20 or 30 mg/day, or 40 or 60 mg/day) or one dosage range of clomipramine (60 or 90 mg/day). After an 8-week acute treatment period, 279 patients agreed to continue their double-blind treatment at the assigned dose. Patients receiving clomipramine or the two highest dosage ranges of citalopram showed significant improvement compared with placebo in a variety of anxiety rating scales including the Clinical Anxiety Scale (CAS) panic attack item. The authors concluded that citalopram in the dosage range of 20–60 mg/day was an effective long-term therapy for the management of panic disorder (Lepola et al. 1998).

In a single-blind variable-dosage study (Perna et al. 2001), 58 patients were randomly assigned to groups for treatment with either citalopram or paroxetine (both at doses of 20–50 mg/day). By day 60, 86% of patients receiving citalopram and 84% of patients receiving paroxetine responded well to treatment as determined by a 50% reduction from baseline of both the Panic Associated Symptoms Scale (PASS) and the Sheehan Disability Scale (SDS) global scores (Perna et al. 2001). There was no significant difference found between the two drugs. While both drugs were well tolerated, sexual side effects and weight gain were frequent. By day 60 of the study, 41% of patients on citalopram and 48% of patients on paroxetine reported sexual dysfunctions, and 37% of patients on citalopram and 40% of patients on paroxetine reported weight gain. An additional small-scale study (Rampello et al. 2006) demonstrated that citalopram and *S*-citalopram had similar effectiveness in the management of panic attacks, with a suggestion that *S*-citalopram had a faster onset of action. This study is described in more detail in the *S*-citalopram section below. While these studies have a limited number of subjects and lack a placebo control group, they do provide a preliminary indication that citalopram may be effective in the treatment of panic disorder. To conclusively demonstrate the effectiveness of citalopram, additional large placebo-controlled studies are necessary.

S-Citalopram

S-citalopram has been evaluated for effectiveness in the treatment of panic disorder in two clinical trials. In a 10-week randomized, double-blind, placebo-controlled, flexible-dosage study *S*-citalopram (5–10 mg/day) was compared with citalopram (10–20 mg/day) and placebo in patients with a diagnosis of panic disorder with or without agoraphobia (Stahl et al. 2003). The primary measure of efficacy was the number of panic attacks at week 10 relative to baseline as assessed by the Modified Sheehan Panic and Anticipatory Anxiety Scale (PAAS). The relative panic attack frequency was

significantly lower in the *S*-citalopram group (*n* = 125) compared with the placebo group (*n* = 114; *P* = 0.04), and at the end of the study there was a greater proportion of patients with zero panic attacks in the *S*-citalopram group (50%) compared with the placebo group (38%) that was marginally significant (*P* = 0.051). There was no significant difference with the citalopram treatment group (*n* = 112) in these two measures. Both *S*-citalopram and citalopram significantly improved panic disorder symptoms and severity relative to placebo at the end of the study, as measured by several different assessment scales.

The second clinical study was a smaller-scale 8-week open-label community-based comparison trial that examined the effectiveness of *S*-citalopram (10 mg/day; *n* = 20) and citalopram (20 mg/day; *n* = 20) in the treatment of panic attacks in the elderly (Rampello et al. 2006). Both drugs produced a similar decrease in the weekly rate of panic attacks and decreases in both Ham-A and Cooper Disability Scores, with no significant difference between drugs at the end of the study. However, a significant improvement from baseline was evident for *S*-citalopram as early as 2 weeks (*P* <0.001), whereas the effectiveness of citalopram was not evident until 4 weeks (*P* <0.01), suggesting a faster onset of clinical effect with *S*-citalopram.

Social Anxiety Disorder

Citalopram

A large-scale double-blind, placebo-controlled study demonstrated that paroxetine is effective in the treatment of social anxiety disorder, suggesting that other SSRIs may be effective in the treatment of this disorder (M. B. Stein et al. 1998). While there are no such published large-scale, placebo-controlled studies with citalopram, case reports indicate that citalopram may have efficacy in the treatment of social anxiety disorder (Bouwer and Stein 1998; Lepola et al. 1994, 1996; Simon et al. 2001). In addition, one 12-week, small-scale (*N* = 21) flexible-dose, open-label study demonstrated the effectiveness of citalopram (20–60 mg/day) in relieving the symptoms of social anxiety disorder in patients who suffered from comorbid depression (Schneier et al. 2003).

S-Citalopram

Two large-scale multinational, multicenter clinical trials have demonstrated the effectiveness of *S*-citalopram in the treatment of social anxiety disorder. In a 24-week fixed-dosage trial (Lader et al. 2004), patients with a diagnosis of social anxiety disorder were randomly assigned to double-blind treatment with placebo (*n* = 166), 5 mg/day *S*-citalopram (*n* = 167), 10 mg/day *S*-citalopram (*n* = 167), 20 mg/day *S*-citalopram (*n* = 170), or 20 mg/day paroxetine (*n* = 169). Based on the mean change from baseline in the Liebowitz Social Anxiety Scale (LSAS) total score, there was a statistically superior therapeutic effect compared with placebo by week 12 using observed cases analysis for all doses of *S*-citalopram and the 20 mg/day paroxetine. Further improvement was seen by week 24 for all doses of *S*-citalopram and paroxetine, and the 20 mg/day *S*-citalopram was superior to the 20 mg/day paroxetine. The mean reduction in LSAS score from baseline was significant for 5 mg/day and 20 mg/day *S*-citalopram by week 2 and for 10 mg/day *S*-citalopram by week 4. Finally, treatment with 20mg/day *S*-citalopram showed superiority over 20 mg/day paroxetine by week 16. In a second study of 12 weeks (Kasper et al. 2005b), patients were randomly assigned to double-blind treatment with either placebo (*n* = 177) or 10–20 mg/day *S*-citalopram (*n* = 181). Based on the mean change from baseline in the LSAS score, *S*-citalopram produced a superior therapeutic response compared with placebo (*P* = 0.005). A greater percentage of patients responded to treatment (defined as a CGI-I score of 1 or 2) from the *S*-citalopram group (54%) compared with the placebo group (39%; *P* <0.001). This improvement was associated with a lessening of symptoms as measured with work and social components of the SDS.

Because social anxiety disorder is a chronic illness, pharmacological treatment should be effective

over extended periods of time to prevent illness relapse. One study has examined the ability of *S*-citalopram treatment for up to 24 weeks to prevent relapse of social anxiety disorder following successful short-term therapy (Montgomery et al. 2005). In the first phase of this trial, patients took part in a 12-week open-label, flexible-dosage (10–20 mg/day *S*-citalopram) study. Of the 517 patients who enrolled in the study, 371 responded to treatment. The responders were then entered into a 24-week double-blind trial, receiving either a fixed-dosage of *S*-citalopram (10 or 20 mg/day; $n = 190$) or placebo ($n = 181$). Significantly fewer patients relapsed at both doses of *S*-citalopram (22%) compared with placebo (50%), with relapse being 2.8 times more likely with placebo treatment than with *S*-citalopram treatment ($P < 0.001$).

Anxiety Associated With Major Depression

Citalopram

A retrospective study of 2,000 depressed patients enrolled in eight different double-blind, placebo-controlled clinical trials revealed that citalopram was effective in relieving the symptoms of anxiety in depressed patients based on a greater decrease from baseline in the anxiety factor of the Ham-D compared with placebo (Flicker and Hakkarainen 1998). The incidence of activating side effects (i.e., insomnia, nervousness, anxiety, agitation, and tremor) was similar to that for placebo. The authors concluded that citalopram was effective in the treatment of anxious depression, with a low potential for producing activating side effects. Another double-blind, placebo-controlled study involving 323 patients diagnosed with DSM-IV-defined major depression revealed a significant antianxiety effect of citalopram (20–60 mg/day) compared with placebo based on decreases in the Ham-A score (Stahl 2000). In the same study, sertraline (50–150 mg/day) did not show significant antianxiety activity.

S-Citalopram

The effectiveness of *S*-citalopram in the treatment of anxiety symptoms associated with major depressive disorder has been evaluated in a pooled analysis of five clinical trials (Bandelow et al. 2007). These placebo-controlled trials were originally designed to examine the effectiveness of *S*-citalopram in treating major depression, and three of them included a comparison to citalopram. In the pooled analysis, *S*-citalopram (10–20 mg/day) was consistently superior to placebo in relieving the anxious symptoms associated with the depression as revealed in several different assessments of anxiousness. For example, when pooling data from all five trials and using the change from baseline in inner tension score (item 3 from MADRS), *S*-citalopram ($n = 850$) was superior to placebo ($n = 737$) from week 1 through week 8. Citalopram also showed superiority to placebo in the majority of the anxiety measures in the three clinical trials in which it was included. The analyses presented in this pooled study indicate that *S*-citalopram is effective in relieving anxiety symptoms in depressed patients.

Eating Disorders

Citalopram

SSRIs are often used in the treatment of eating disorders such as bulimia, anorexia, and binge-eating disorder (Carter et al. 2003). However, the effectiveness of citalopram in the treatment of eating disorders has not been tested in any published large-scale trials. A small-scale ($n = 18$) open-label trial indicated that citalopram (20 mg/day) may be effective in the treatment of bulimia and anorexia (Calandra et al. 1999), although another report questioned the effectiveness of citalopram in the treatment of anorexia (Bergh et al. 1996). More recently, a small-scale, double-blind clinical trial was performed in which patients diagnosed with binge-eating disorder were randomly assigned to receive citalopram (20–60 mg/day; $n = 19$) or placebo ($n = 19$) (McElroy et al. 2003). Compared with patients on placebo, patients receiving citalopram for 6 weeks significantly improved based on a variety of

measures including frequency of binge eating ($P = 0.003$), frequency of binge days ($P < 0.001$), body mass index ($P < 0.001$), and weight ($P < 0.001$). In the treatment of bulimia nervosa there is one published single-blind trial that compared citalopram (20–40 mg/day; $n = 19$) with fluoxetine (20–60 mg/day; $n = 18$) and demonstrated a similar efficacy between these two drugs in the relief of eating psychopathology (Leombruni et al. 2006). These studies are preliminary, and a clear demonstration of the effectiveness of citalopram in the treatment of eating disorders requires further study.

S-Citalopram

One small-scale study has examined the effectiveness of high-dose *S*-citalopram therapy in the treatment of binge eating disorder associated with obesity (Guerdjikova et al. 2008). In this 12-week double-blind study treatment with a flexible dosage of *S*-citalopram (10–30 mg/day; $n = 21$) was compared with placebo ($n = 23$). *S*-citalopram treatment was associated with significant reductions in weight, body mass index, and global severity of illness scores; however, due to limitations in statistical power, the authors could not make conclusions about the ability of *S*-citalopram to reduce the frequency of binge eating. Clearly, additional larger clinical trials are necessary to assess the effectiveness of *S*-citalopram in the treatment of eating disorders.

Poststroke Depression

Citalopram

Depression is a common complication that occurs in approximately 20% of stroke victims (Robinson 2003). Citalopram has demonstrated efficacy in the treatment of poststroke depression in a controlled clinical trial. A 6-week double-blind, placebo-controlled study demonstrated that citalopram (10–40 mg/day) was significantly better than placebo in treating poststroke depression (Andersen et al. 1994). Significant improvement was seen with the Ham-D and MADRS scores compared with placebo. This significant effect was seen only in patients who became depressed 7 weeks or more after the stroke. For patients who became depressed 2–6 weeks after the stroke, recovery from depression occurred within 1 month, independent of the treatment, indicating a high level of spontaneous recovery. Additionally, in a randomized, double-blind study in which citalopram (20 mg/day) was compared only with reboxetine (4 mg/day), 16 weeks of citalopram treatment was particularly effective in poststroke patients suffering from anxious depression (Rampello et al. 2004). In the treatment of poststroke crying, a small ($n = 16$) double-blind, placebo-controlled study demonstrated that citalopram (10–20 mg/day) was effective in relieving poststroke pathological crying compared with placebo (Andersen et al. 1993). In a variable-dose study involving 32 patients receiving either citalopram or paroxetine, citalopram (10–40 mg/day) was comparable to paroxetine (10–40 mg/day) in relieving the symptoms of pathological crying or laughing following brain injury (Muller et al. 1999).

S-Citalopram

The effectiveness of *S*-citalopram in the treatment of poststroke depression has been tested in one double-blind, placebo-controlled clinical trial (Robinson et al. 2008). This 12-month trial, conducted with nondepressed patients within 3 months of an acute stroke, contained a double-blinded comparison between a placebo treatment group ($n = 58$) and an *S*-citalopram treatment group (5–10 mg/day; $n = 59$) and a nonblinded comparison with a problem-solving therapy group ($n = 59$). Using a conservative intention-to-treat method of analyzing the data, the study showed that the likelihood of developing depression was greater in the placebo group (34.5%) compared with the *S*-citalopram group (23.1%; $P < 0.01$). While the problem-solving therapy group had a lower incidence of depression (30.5%) compared with the placebo group, the difference did not reach statistical significance. This study provides a preliminary indication that *S*-citalopram therapy may afford some protection against the development of poststroke depression, but additional studies are necessary to conclusively demonstrate this.

Dementia

Citalopram

The effectiveness of citalopram in relieving various emotional disturbances associated with dementia was compared with placebo in a double-blind multicenter clinical trial. Of the 89 patients included in the efficacy analyses, 65 had senile dementia of the Alzheimer type (SDAT)/Alzheimer's disease (AD) and 24 had vascular dementia; the average age of the patients was 77.6 years. In the patients with SDAT/AD, treatment with citalopram (10–30 mg/day) significantly improved emotional bluntness, confusion, irritability, anxiety, fear/panic, depressed mood, and restlessness compared with placebo (Nyth and Gottfries 1990). This improvement was not seen in patients suffering from vascular dementia. A separate 6-week placebo-controlled study examined the effects of citalopram in elderly depressed patients (*n* = 149) with and without dementia. In this study, depressed patients with and without dementia receiving either 20 mg/day or 30 mg/day of citalopram showed significantly greater improvement in depressive symptoms compared with those receiving placebo. It is noteworthy that there was also improvement on several measures on the Gottfries-Brane-Steen scale of cognitive function in the subgroup of depressed patients with dementia (Nyth et al. 1992). In another randomized, double-blind trial involving 336 elderly depressed patients with and without dementia, 12 weeks of treatment with either citalopram (20–40 mg/day) or mianserin (30–60 mg/day) was effective in relieving the symptoms of depression, although it should be noted that the magnitude of response was lower in the patients with dementia (Karlsson et al. 2000). Finally, a randomized, double-blind, placebo-controlled trial involving 85 nondepressed elderly inpatients with dementia compared the effectiveness of citalopram and perphenazine in the treatment of behavioral disturbances. In this study, citalopram (20 mg/day) was more effective than perphenazine (0.1 mg/kg/day) in the acute relief of both psychotic symptoms and emotional disturbances associated with dementia (Pollock et al. 2002). Taken together, these studies provide a preliminary indication that citalopram may be effective in the management of the emotional disturbances, including depression, associated with dementia in the elderly.

S-Citalopram

There are no published large-scale clinical trials evaluating the effectiveness of *S*-citalopram in treating mood disturbances associated with dementia in elderly patients. In an 8-week open-label treatment study involving 12 patients diagnosed with depression of AD (for definition, see Olin et al. 2002), *S*-citalopram (10–20 mg/day) was effective in relieving the symptoms of depression but showed no improvement in cognition (V. Rao et al. 2006).

SIDE EFFECTS AND TOXICOLOGY

Citalopram

In a meta-analysis of 746 depressed patients who participated in several short-term clinical trials, the most common adverse events associated with citalopram were nausea and vomiting (20%), increased sweating (18%), and dry mouth and headache (17%) (Baldwin and Johnson 1995). Analysis of an integrated safety database, which includes data from 3,107 patients enrolled in 24 clinical trials, indicated that in placebo-controlled trials, nausea, dry mouth, somnolence, increased sweating, tremor, diarrhea, and ejaculatory failure of mild to moderate severity occurred with significantly greater frequency with citalopram compared with placebo (Muldoon 1996). The incidences of these adverse events were less than 10% above those seen with placebo and were comparable to those seen with other SSRIs. Citalopram had a tolerability that was superior to that of the TCAs, with the exception that nausea and ejaculatory failure occurred with a 5% greater frequency with citalopram (Keller 2000).

It is well known that administration of SSRIs can produce sexual side effects such as anorgasmia and

ejaculatory failure. Some reports have suggested that citalopram may be associated with a lower incidence of sexual side effects (Waldinger et al. 2001). However, other reports indicate that the rate of sexual side effects seen with citalopram is similar to that seen with other SSRIs (Ekselius and von Knorring 2001). For example, using the Changes in Sexual Functioning Questionnaire (CSFQ), the percentage of patients receiving citalopram that rated as experiencing sexual dysfunction was approximately 40% in the overall patient group and approximately 30% in the subpopulation of patients free of other probable causes of sexual dysfunction. These two rates were similar to those reported for all other SSRIs used in the study (Clayton et al. 2002).

At therapeutic doses, citalopram does not have significant cardiovascular effects. Analysis of ECG data from prospective studies in healthy volunteers and patients as well as retrospective ECG data from all clinical trials conducted from 1978 to 1996 (a total of 40 trials) concluded that citalopram was without significant effect on cardiac conduction and repolarization (Rasmussen et al. 1999). The only significant cardiovascular effect was a small reduction in heart rate (≤8 beats/minute). There are some reports of citalopram producing cardiovascular abnormalities in association with overdose (Catalano et al. 2001). Citalopram has been associated with ECG abnormalities and seizure at doses over 600 mg/day.

S-Citalopram

In general, the side effects associated with *S*-citalopram are similar to those observed with citalopram. In the three placebo-controlled clinical trials that have been performed with *S*-citalopram, a dosage of 10 mg/day produced rates of discontinuation due to adverse events that did not differ from those in the placebo group (Burke et al. 2002; Montgomery et al. 2001b; Wade et al. 2002). In the one trial that included an *S*-citalopram dosage of 20 mg/day, the rate of discontinuation was 10.4%, which was greater than the placebo rate of 2.5% (Burke et al. 2002). In addition, the rate of adverse events overall in the 20 mg/day *S*-citalopram group (85.6%) was significantly greater than that in the placebo group (70.5%). Regardless of dose, the adverse events that have been reported to occur more frequently with *S*-citalopram compared with placebo are nausea, diarrhea, insomnia, dry mouth, and ejaculatory disorder, with nausea being reported most frequently, at a rate of 15% (McRae 2002). No published studies have reported clinically significant findings in laboratory test values, vital signs, weight gain or loss, or electrocardiogram values.

Specific Effects and Syndromes

Hyponatremia

The use of SSRIs as a class has been associated with hyponatremia (Guay 2000) that is defined as a serum sodium concentration below 130 mEq/L and is characterized initially by nausea and malaise and subsequently by headache, lethargy, muscle cramps, disorientation, and restlessness. If serum sodium concentrations fall below 120 mEq/L, this can lead to seizures, coma, and respiratory arrest. The reported frequency of hyponatremia associated with SSRI use varies considerably, from 0.5% to 32%, with a greater incidence associated with older patients. The mechanism for SSRI-induced hyponatremia is unclear but may result from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Citalopram and *S*-citalopram have been shown to produce hyponatremia in case reports involving the elderly (Covyeou and Jackson 2007; Fisher et al. 2002), and this information was recently reviewed (Jacob and Spinler 2006). In addition to advanced age, other factors that may increase the likelihood of hyponatremia include female gender, concurrent diuretic use, low body weight, and recent pneumonia. Treatment of SSRI-induced hyponatremia usually involves fluid restriction and/or administration of a loop diuretic such as furosemide and may include discontinuation of the SSRI.

Discontinuation Syndrome

The abrupt cessation of antidepressant therapy can result in a "discontinuation syndrome" characterized by dizziness, nausea and vomiting, lethargy, and flu-like symptoms. Other effects include dysphoric mood, irritability, agitation, paresthesias (such as electric shock sensations), anxiety, confusion, headache, emotional lability, insomnia, and hypomania. This syndrome is more common with short-half-life SSRIs such as paroxetine and less common with long-half-life SSRIs such as fluoxetine. The data obtained from clinical trials suggest that the adverse events associated with discontinuation of citalopram tend to be mild and transient (Markowitz et al. 2000; Montgomery et al. 1993). In terms of *S*-citalopram, a meta-analysis of five clinical studies on treatment of major depressive disorder, GAD, and social anxiety disorder that ranged in duration from 8 weeks to 27 weeks showed that *S*-citalopram (5–20 mg/day; *n* = 1,051) had significantly fewer discontinuation symptoms compared with paroxetine (20–40 mg/day; *n* = 336) and venlafaxine (75–150 mg/day; *n* = 124), two short-half-life antidepressants commonly associated with treatment discontinuation syndrome (Baldwin et al. 2007). However, *S*-citalopram did show significantly more discontinuation symptoms compared with placebo (*n* = 239), with some of the more common symptoms being dizziness, irritability, nervousness, and sweating. The incidence of these symptoms tended to increase with the dose of *S*-citalopram that was being administered prior to discontinuation. Dose tapering is recommended for patients discontinuing treatment with citalopram or *S*-citalopram.

Treatment-Emergent Suicidal Ideation and Suicide

Considerable attention has been focused in recent years on the possibility that antidepressant drugs, especially SSRIs, may lead to an increase in suicidal ideation in some patients, particularly at the onset of therapy (Jick et al. 2004). This issue is of great concern in young patients and was described earlier in the chapter (see section "Depression in Children and Adolescents"). In studies involving adults, several meta-analyses of large-scale clinical trial data obtained with a variety of antidepressants have demonstrated no increase in the relative risk of suicide compared with placebo (Beasley et al. 1991; Khan et al. 2003; Storosum et al. 2001). In the case of citalopram, analyses of data obtained from 17 controlled clinical trials involving 5,000 patients indicate that the group of patients receiving citalopram had the lowest rate of suicide compared with the groups receiving placebo, tricyclic antidepressants, or other SSRIs (Nemeroff 2003). The risk of suicide associated with *S*-citalopram was evaluated based on data contained in the Summary Basis of Approval reports obtained from the FDA (Khan and Schwartz 2007). This study did not detect a significantly greater rate of suicide in the *S*-citalopram group compared with either the citalopram or the placebo group. There was also no indication that *S*-citalopram increased suicidal behavior in major depressive disorder and anxiety disorders in a meta-analysis of the *S*-citalopram clinical trials database consisting of 2,277 *S*-citalopram-treated patients and 1,814 placebo-treated patients (Pedersen 2005).

While the data do not indicate a significantly greater risk of suicide in patients receiving either citalopram or *S*-citalopram compared with placebo, most antidepressant studies do show that a limited number of patients will exhibit increased suicidal ideation upon initiation of therapy. Family and twin studies provide some evidence of a genetic influence on suicidal behavior, and it has been postulated that treatment-emergent suicidal ideation may also be genetically linked. Interestingly, a recent study involving patients participating in the STAR*D trial demonstrated a significant association between citalopram treatment-emergent suicidal ideation in men and polymorphisms near the gene for the transcription factor CREB (Perlis et al. 2007). This protein is of great interest because it mediates the effects of second messengers on new gene transcription and has been implicated in antidepressant action and suicide (Dowlatshahi et al. 1998; Dwivedi et al. 2003).

DRUG–DRUG INTERACTIONS

Because multiple P450 enzymes (CYP2C19, CYP3A4, and CYP2D6) contribute equally to the metabolism of citalopram and *S*-citalopram, inhibition of any one of these enzymes by another drug is

unlikely to significantly impact the overall metabolism of citalopram or *S*-citalopram. Consistent with this, there are relatively few reports in the literature of drug–drug interactions involving citalopram or *S*-citalopram.

Antipsychotics

While citalopram has not been shown to increase the levels of concomitantly administered antipsychotics (Syvalahti et al. 1997), there are studies showing that the administration of antipsychotics, including levomepromazine and alimemazine, increases the levels of citalopram and its major metabolite DCT (Gram et al. 1993; Oyehaug et al. 1984). Additionally, a study involving 169 psychiatric patients demonstrated that concomitant administration of a neuroleptic, a benzodiazepine, or a TCA resulted in small but significant elevations of citalopram concentrations (Leinonen et al. 1996).

Antidepressants

The administration of relatively high doses of citalopram (40–60 mg/day) did not affect the plasma concentrations of amitriptyline, clomipramine, or maprotiline in five case studies (Baettig et al. 1993). In contrast, citalopram was shown to increase the level of the metabolite of imipramine, desipramine, by 50% without changing the concentration of the parent compound (Gram et al. 1993). This latter finding may result from competition between DCT, the major metabolite of citalopram, and desipramine for metabolism by CYP2D6. In terms of SSRIs, coadministration of citalopram with fluoxetine or fluvoxamine significantly increased the plasma concentration of the *S*-citalopram enantiomer. The elevated *S*-citalopram levels most likely result from the known inhibitory activity of fluvoxamine and fluoxetine on the activity of CYP2C19 and CYP2D6 (Bondolfi et al. 1996, 2000).

Benzodiazepines and Mood Stabilizers

There is little evidence of clinically significant pharmacokinetic interactions between citalopram and either benzodiazepines or mood stabilizers, including lithium (Baumann et al. 1996; Gram et al. 1993; Sproule et al. 1997).

Monoamine Oxidase Inhibitors

Because of the possibility of a potentially fatal phamacodynamic interaction resulting in the serotonin syndrome, neither citalopram nor *S*-citalopram should be administered with an MAO inhibitor or within 14 days of discontinuing an MAO inhibitor.

CONCLUSION

Citalopram and *S*-citalopram are highly selective 5-HT reuptake inhibitors that are well tolerated and effective in the treatment of depression, with *S*-citalopram also having proven efficacy in large-scale clinical trials in the treatment of GAD. While the use of citalopram and *S*-citalopram in the treatment of other psychiatric conditions has not been as thoroughly studied, the few well-controlled trials that have been completed suggest that both drugs may have a significant role in treating a wide range of psychiatric illnesses, including panic disorder, social anxiety disorder, anxiety associated with depression, and OCD. An advantage of citalopram and *S*-citalopram compared with some other common SSRIs is a relatively weak inhibition of liver cytochrome P450 enzymes, which reduces the potential for adverse pharmacokinetic drug–drug interactions. In addition, because *S*-citalopram does not share with citalopram a modest affinity for the histamine H_1 receptor, it may have a lower potential for antihistaminergic side effects compared with citalopram, a difference that has yet to be demonstrated in a clinical trial. There are a number of clinical trials comparing *S*-citalopram with a variety of other antidepressants, including citalopram and venlafaxine, that suggest that *S*-citalopram may have a faster onset of antidepressant efficacy and modest superiority in the treatment of the severely depressed. More extensive experience with *S*-citalopram is necessary to conclusively

determine whether its statistically significant superiority to citalopram and other SSRIs in clinical studies translates into the "real world" of psychiatric practice.

Chapter 18. Monoamine Oxidase Inhibitors

HISTORY AND DISCOVERY

Monoamine oxidase inhibitors (MAOIs) were first identified as effective antidepressants in the late 1950s. An early report suggested that iproniazid, an antitubercular agent, had mood-elevating properties in patients who had been treated for tuberculosis (Bloch et al. 1954). Following these observations, two studies confirmed that iproniazid did indeed have antidepressant properties (Crane 1957; Kline 1958). Zeller (1963) reported that iproniazid caused potent inhibition of monoamine oxidase (MAO) enzymes both in vivo and in vitro in the brain. He also reported that the medication reversed some of the actions of reserpine. Because reserpine produced significant depression as a side effect, it was suggested that iproniazid might have mood-elevating properties.

The use of iproniazid soon fell into disfavor because of its significant hepatotoxicity. Other MAOIs, both hydrazine derivatives (e.g., isocarboxazid and phenylhydrazine) and nonhydrazine derivatives (e.g., tranylcypromine), were introduced. These MAOIs were not specific for any subtype of MAO enzyme, and they were irreversible inhibitors of MAO (see next section, "Monoamine Oxidase"). Their use has been rather limited because hypertensive crisis by the MAOIs may occur in some patients from potentiation of the pressor effects of amines (such as tyramine) in food (Blackwell et al. 1967).

In the past few years, there has been a resurgence of interest in the development of new monoamine oxidase inhibitors—that is, in those MAOIs that are more selective for specific subtypes of MAO enzyme and in those that are reversible in nature. Newer MAOIs, such as L-deprenyl (selegiline hydrochloride), a monoamine oxidase B (MAO-B) inhibitor, have been introduced (Table 18–1). Reversible monoamine oxidase A (MAO-A) inhibitors, such as moclobemide, have been introduced in Europe but are not yet available in the United States.

MONOAMINE OXIDASE

A and B Isoenzymes

MAO is widely distributed in mammals. Two isoenzymes, MAO-A and MAO-B, are of special interest in psychiatry (Cesura and Pletscher 1992). Both are present in the central nervous system (CNS) and in some peripheral organs. Both MAO-A and MAO-B are present in discrete cell populations within the CNS. MAO-A is present in both dopamine (DA) and norepinephrine (NE) neurons, whereas MAO-B is present to a greater extent in serotonin (5-HT)–containing neurons. They are also present in nonaminergic neurons in various subcortical regions of the brain. Glial cells also express MAO-A and MAO-B (Cesura and Pletscher 1992).

The physiological functions of these two isoenzymes have not been fully elucidated. The main substrates for MAO-A are epinephrine, NE, and 5-HT. The main substrates for MAO-B are phenylethylamine, phenylethanolamine, tyramine, and benzylamine. DA and tryptamine are metabolized by both isoenzymes. The localization of the MAO subtypes does not fully correspond to the neurons containing the substrates. The reason for this discrepancy is unknown. The occurrence of the MAO-B form in 5-HT neurons may actually protect these neurons from amines (other than 5-HT) that could be toxic to them (Cesura and Pletscher 1992).

The primary structures of MAO-A and MAO-B have been fully described. MAO-A has 527 amino acids, and MAO-B has 520 amino acids. About 70% of the amino acid sequence of the two forms is homologous. The genes for both isoenzymes are located on the short arm of the human X chromosome. MAO-A and MAO-B are linked and have been located in the XP11.23–P11 and XP22.1 regions, respectively. The genes are about 70 kilobases and consist of about 15 exons and 14 introns. MAO-A has two messenger RNA (mRNA) transcripts of 2.1 and 5.0 kilobytes in length. MAO-B has a 3-kb mRNA single transcript (Cesura and Pletscher 1992). A rare inherited disorder, Norrie's disease, is characterized by deletion of both genes; patients with this disorder have very severe mental retardation and blindness.

The subunit composition of MAO is unknown. The enzyme is primarily found in the outer mitochondrial membrane; flavin adenine dinucleotide (FAD) is a cofactor for both MAO-A and MAO-B.

Because the cofactor domain is the same for both of the MAO isoenzymes, the structural differences responsible for substrate specificity are believed to lie in regions of the protein that bind to the hydrophobic moiety of the substrate. Although DA is considered to be a mixed substrate for both MAO-A and MAO-B, the breakdown of DA in the striatal regions of the brain is preferentially by MAO-B. In other regions, MAO-A may be more important. There may be regional differences as to which isoenzyme is responsible for the metabolism of other biogenic amines that are substrates for both forms of MAO (Cesura and Pletscher 1992).

Enzyme Kinetics

The enzyme kinetics of MAO-A have not been well studied. The enzyme kinetics for MAO-B, for which more information is available, depend on the nature of the substrate. Some substrates (e.g., tyramine) go through ping-pong mechanisms characterized by first oxidation of the amine to the imine form that is subsequently released from the reduced enzyme before reoxidation of the latter occurs. Other substrates (e.g., benzylamine) involve formation of a tertiary complex with the enzyme and oxygen (Husain et al. 1982; Pearce and Roth 1985; Ramsay and Singer 1991).

MECHANISM OF ACTION

The target function of MAOIs is regulation of the monoamine content within the nervous system. Because MAO is bound to the outer surface of the plasma membrane of the mitochondria, in neurons MAO is unable to deaminate amines that are present inside stored vesicles and can metabolize only amines that are present in the cytoplasm. As a result, MAO maintains a low cytoplasmic concentration of amines within the cells. Inhibition of neuronal MAO produces an increase in the amine content in

the cytoplasm. Initially, it was believed that the therapeutic action of MAOIs was a result of this amine accumulation (Finberg and Youdim 1984; Murphy et al. 1984, 1987). More recently, it has been suggested that secondary adaptive mechanisms may be important for the antidepressant action of these agents.

After several weeks of treatment, MAOIs produce effects, such as a reduction in the number of β -adrenoreceptors, α1- and α2-adrenoreceptors, and serotonin1 (5-HT_1) and serotonin2 (5-HT_2) receptors. These changes are similar to those produced by the chronic use of tricyclic antidepressants (TCAs) and other antidepressant treatment (DaPrada et al. 1984, 1989).

MAOIs can be subdivided on the basis of not only the particular type of enzyme inhibition but also the type of inhibition they produce (reversible or irreversible). The reversible MAOIs are basically chemically inert substrate analogs. MAOIs are recognized as substrates by the enzyme and are converted into intermediates by the normal mechanism. These converted compounds react to the inactive site of the enzyme and form a stable bound enzyme. This effect occurs gradually, and there is usually a correlation between the plasma concentration of the reversible inhibitors and pharmacological action.

PHARMACOLOGICAL PROFILE

The classic MAOIs inhibit both forms of the enzyme and are divided into two main subtypes: hydrazine and nonhydrazine derivatives. The hydrazine derivatives, two of which (phenelzine and isocarboxazid) are currently available, are related to iproniazid. The nonhydrazine irreversible MAOI is tranylcypromine, which is chemically similar to amphetamine. Clorgyline is an example of an irreversible inhibitor of MAO-A, whereas selegiline is an irreversible inhibitor of MAO-B. The only reversible inhibitor of MAO-A available anywhere is moclobemide.

Three classic MAOIs (i.e., tranylcypromine, phenelzine, and isocarboxazid) are of clinical interest. Clinicians must recognize that these drugs not only inhibit MAO but also exert other actions that may be clinically relevant. Thus, these compounds can block MAO uptake—tranylcypromine more than isocarboxazid or phenelzine. In addition, because tranylcypromine is structurally similar to amphetamine, it is believed to exert stimulant-like actions in the brain. Many issues are common to all three of these MAOIs.

INDICATIONS AND EFFICACY

Major and Atypical Depression

Many studies have examined the efficacy of MAOIs in the treatment of different types of depression. MAOIs have been effective in the treatment of major depression or atypical depression (Davidson et al. 1987a; Himmelhoch et al. 1982, 1991; Johnstone 1975; Johnstone and Marsh 1973; McGrath et al. 1986; Paykel et al. 1982; Quitkin et al. 1979, 1990, 1991; Rowan et al. 1981; Thase et al. 1992; Vallejo et al. 1987; White et al. 1984); Zisook et al. 1985). Although early studies of relatively low-dose regimens suggested that the efficacy of MAOIs was lower than that of TCAs, more recent studies have documented that their efficacy is comparable (Table 18–2).

Note. GAD = generalized anxiety disorder; OCD = obsessive-compulsive disorder.
[a]Selegiline is the only MAOI that is useful in the treatment of Parkinson's disease.

Quitkin et al. (1979, 1991) reviewed both phenelzine and tranylcypromine studies in patients with either atypical neurotic depression or melancholic depression. The authors reported that phenelzine appeared to be effective for the treatment of atypical depression.

Relatively few studies of endogenous depression in patients have been done. From the limited number of initial patient studies, it is difficult to conclude that phenelzine is effective in the treatment of these patients. In addition, very few well-controlled studies of tranylcypromine, compared with placebo, have been done. Three of the four studies that compared tranylcypromine with placebo showed that tranylcypromine was more effective. In one study, a nonsignificant trend was found favoring tranylcypromine. More recently, studies have documented the efficacy of tranylcypromine in treating anergic depression and, at high doses, treatment-resistant depression (Himmelhoch et al. 1982, 1991; Thase et al. 1992; White et al. 1984). In the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, patients who had failed to respond to at least three treatment options were randomly assigned to tranylcypromine or a combination of venlafaxine and mirtazapine. Remission rates were modest for both the tranylcypromine group and the extended-release venlafaxine plus mirtazapine group, and the rates were not statistically different between groups (McGrath et al. 2006).

The heterogeneity of acetylation rate may account for some of the variance in response to phenelzine (Johnstone 1975; Johnstone and Marsh 1973; Paykel et al. 1982; Rowan et al. 1981). One-half of the patients in a given population are often slow acetylators. An initial study by Johnstone and Marsh (1973) suggested that slow acetylators improve more with phenelzine than do fast acetylators. Other groups have been unable to confirm the relation between acetylation, acetylator type, and response to MAOIs.

MAOIs are used in a wide range of psychiatric disorders. Early studies suggested that MAOIs are particularly effective in patients who have atypical depression, originally defined as depression with anxiety or chronic pain, reversed vegetative symptoms, and rejection sensitivity (Quitkin et al. 1990).

The concept of atypical depression remains controversial and has not been completely validated. In general, patients with atypical depression have an earlier age at onset than do patients with melancholic depression, and the prevalence of dysthymia, alcohol abuse, sociopathy, and atypical depression is increased in the relatives of patients with atypical depression. The best differentiating criterion appears to be that phenelzine and other irreversible MAOIs are more effective than TCAs in treating these patients (Cesura and Pletscher 1992; Quitkin et al. 1990; Zisook et al. 1985).

Some studies have also suggested that MAOIs are effective in treating typical major depression and melancholic depression (Davidson et al. 1987a; McGrath et al. 1986; Vallejo et al. 1987).

Panic Disorder

Both single- and double-blind studies have found that phenelzine and iproniazid are effective in treating panic disorder (Lydiard et al. 1989; Quitkin et al. 1990; Tyrer et al. 1973). About 50%–60% of patients with panic disorder respond to MAOIs. In the early stages of treatment, patients may have

a worsening of symptoms. This is reduced in clinical practice by combining the MAOI with a benzodiazepine for the initial phase of the study. It has been suggested that in addition to its antipanic effect, phenelzine has an antiphobic action (Kelly et al. 1971). The time course of effect and the dose used are similar to those for major depression.

Social Phobia

Liebowitz et al. (1992) reported that phenelzine is effective in treating social phobia. In an open-label study, Versiani et al. (1988) suggested that tranylcypromine is effective. Versiani et al. (1992) also demonstrated the efficacy of moclobemide in a double-blind study. In clinical experience, about 50% of patients respond to MAOIs, and the onset of response is gradual (usually about 2–3 weeks).

Obsessive-Compulsive Disorder

Although initial case reports suggested that MAOIs may be effective in obsessive-compulsive disorder (Jenike 1981), no double-blind studies have indicated efficacy.

Posttraumatic Stress Disorder

The classic MAOI phenelzine has been proven effective for the treatment of posttraumatic stress disorder (PTSD) in single-blind trials (Davidson et al. 1987b) and a double-blind crossover trial (Kosten et al. 1991).

Generalized Anxiety Disorder

MAOIs are not usually used to treat generalized anxiety disorder (GAD) because the risk–benefit ratio favors the use of selective serotonin reuptake inhibitors (SSRIs), azaspirones, or benzodiazepines. When they are used, MAOIs are used primarily for treating treatment-resistant GAD.

Bulimia Nervosa

Both phenelzine and isocarboxazid have been shown to be effective in treating some symptoms of bulimia nervosa (Kennedy et al. 1988; McElroy et al. 1989; Walsh et al. 1985, 1987).

Premenstrual Dysphoria

Preliminary studies and clinical experience suggest that MAOIs may be effective in the treatment of premenstrual dysphoria (Glick et al. 1991).

Chronic Pain

MAOIs are believed to be effective in the treatment of atypical facial pain and other chronic pain syndromes. However, only limited data on these conditions are available.

Neurological Diseases

The classic MAOIs have not been found to be effective for treating neurological disorders such as Parkinson's disease and Alzheimer's dementia. However, the MAO-B inhibitor selegiline has been shown to be effective in slowing the progression of Parkinson's disease (Cesura and Pletscher 1992), but the mechanism underlying this effect is unknown.

SIDE EFFECTS AND TOXICOLOGY

The side effects of MAOIs are generally more severe or frequent than those of other antidepressants (Zisook 1984). The most frequent side effects include dizziness, headache, dry mouth, insomnia, constipation, blurred vision, nausea, peripheral edema, forgetfulness, fainting spells, trauma, hesitancy of urination, weakness, and myoclonic jerks. Loss of weight and appetite may occur with isocarboxazid use (Davidson and Turnbull 1982). Hepatotoxicity is more rare with the currently available MAOIs, compared with iproniazid. However, liver enzymes, such as aspartate transaminase

(AST) and alanine transaminase (ALT), are elevated in 3%–5% of patients. Liver function tests must be done only when patients have symptoms like malaise, jaundice, and excessive fatigue.

Some side effects first emerge during maintenance treatment (Evans et al. 1982). These side effects include weight gain (which occurs in almost one-half of patients), edema, muscle cramps, carbohydrate craving, sexual dysfunction (usually anorgasmia), pyridoxine deficiency (see Goodheart et al. 1991), hypoglycemia, hypomania, urinary retention, and disorientation. Peripheral neuropathy (Goodheart et al. 1991) and speech blockage (Goldstein and Goldberg 1986) are rare side effects of MAOIs. Weight gain is more of a problem with hydrazine compounds, such as phenelzine, than with tranylcypromine. Therefore, weight gain that is caused by hydrazine derivatives is an indication to switch to tranylcypromine. Edema is also more common with phenelzine than with tranylcypromine.

The management of some of these side effects can be problematic. Orthostatic hypotension is common with MAOIs. Addition of salt and salt-retaining steroids, such as fluorohydrocortisone, is sometimes effective in treating orthostatic hypotension. Elastic support stockings are also helpful. Small amounts of coffee or tea taken during the day also keep the blood pressure elevated. The dose of fluorohydrocortisol should be adjusted carefully because in elderly patients it could provoke cardiac failure resulting from fluid retention.

Sexual dysfunction that occurs with these compounds is also difficult to treat. Common problems include anorgasmia, decreased libido, impotence, and delayed ejaculation (Harrison et al. 1985; Jacobson 1987). Cyproheptadine is sometimes effective in treating sexual dysfunction like anorgasmia. Bethanechol may also be effective in some patients.

Insomnia occasionally occurs as an intermediate or late side effect of these compounds. Changing the time of administration does not seem to help much, although dosage reduction may be helpful. Adding trazodone at bedtime is effective, but this should be done with caution. Myoclonic jerks, peripheral neuropathy, and paresthesia, when present, are also difficult to treat. When a patient has paresthesia, the clinician should evaluate for peripheral neuropathy and pyridoxine deficiency. In general, patients taking MAOIs should also take concomitant pyridoxine therapy. When myoclonic jerks occur, patients can be treated with cyproheptadine.

MAOIs also have the potential to suppress anginal pain; therefore, coronary artery disease could be overlooked or underestimated.

Patients with hyperthyroidism are more sensitive to MAOIs because of their overall sensitivity to pressor amines. MAOIs can also worsen hypoglycemia in patients taking hypoglycemic agents like insulin.

DIETARY INTERACTIONS

After the introduction of MAOIs, several reports of severe headaches in patients who were taking these compounds were published ("Cheese and Tranylcypromine" 1970; Cronin 1965; Hedberg et al. 1966; Simpson and Gratz 1992). These headaches were caused by a drug–food interaction. The risk of such an interaction is highest for tranylcypromine and lower for phenelzine, provided that the dose of the latter remains low. The interaction of MAOIs with food has been attributed to increased tyramine levels. Tyramine, which has a pressor action, is present in a number of foodstuffs. It is normally broken down by the MAO enzymes and has both direct and indirect sympathomimetic actions. The classic explanation of this side effect may not be entirely accurate; in fact, it has been suggested that the potentiation of tyramine by an MAOI may be secondary to increased release of NE rather than to the MAOI. Adrenaline would increase the indirect sympathetic activity of tyramine. The spontaneous occurrence of hypertensive crises in a few patients lends support to this hypothesis (O'Brien et al. 1992; Zajecka and Fawcett 1991).

The tyramine effect of food is potentiated by MAOIs 10- to 20-fold. A mild tyramine interaction occurs

with about 6 mg of tyramine; 10 mg can produce a moderate episode, and 25 mg can produce a severe episode that is characterized by hypertension, occipital headache, palpitations, nausea, vomiting, apprehension, occasional chills, sweating, and restlessness. On examination, neck stiffness, pallor, mild pyrexia, dilated pupils, and motor agitation may be seen. The reaction usually develops within 20–60 minutes after ingestion of food. Occasionally, the reaction can be very severe and may lead to alteration of consciousness, hyperpyrexia, cerebral hemorrhage, and death. Death is exceedingly rare and has been calculated to be about 0.01%–0.02% for all patients taking tranylcypromine.

The classic treatment of the hypertensive reaction is phentolamine (5 mg) administered intravenously (Youdim et al. 1987; Zisook 1984). More recently, nifedipine, a calcium channel blocker, has been shown to be effective. Nifedipine has an onset of action of about 5 minutes, and it lasts approximately 3–5 hours; in fact, some clinicians have suggested that patients should carry nifedipine with them for immediate use in the event of a hypertensive crisis.

Because of the drug interaction of the classic MAOIs with food, clinicians usually make several dietary recommendations (Table 18–3). These recommendations are quite varied.

TABLE 18–3. Food restrictions for monoamine oxidase inhibitors (MAOIs)

To be avoided	To be used in moderation
Cheese (except for cream cheese)	Coffee
Overripe (aged) fruit (e.g., banana peel)	Chocolate
Fava beans	Colas
Sausage, salami	Tea
Sherry, liqueurs	Soy sauce
Sauerkraut	Beer, other wines
Monosodium glutamate	
Pickled fish	
Brewer's yeast	
Beef and chicken liver	
Fermented products	
Red wine	

All of the MAOI diets recommend restriction of cheese (with the exception of cream cheese and cottage cheese), red wine, sherry, liqueurs, pickled fish, overripe (aged) fruit, brewer's yeast, fava beans, beef and chicken liver, and fermented products. Other diets also recommend restriction of all alcoholic beverages, coffee, chocolate, colas, tea, yogurt, soy sauce, avocados, and bananas. The more restrictive the diet, the greater the risk of patient noncompliance. Furthermore, many of the compounds—for example, avocados and bananas—rarely cause hypertensive crisis. For example, an interaction may occur only if overripe fruit is eaten or, in the case of bananas, if the skin is eaten (which is an uncommon practice in the United States). Similarly, unless a person ingests large amounts of caffeine, the interaction is usually not clinically significant.

In evaluating patients who have had a drug–food reaction, it is also important to evaluate the hypertensive reaction and differentiate it from histamine headache, which can occur with an MAOI. Histamine headaches are usually accompanied by hypotension, colic, loose stools, salivation, and lacrimation (Cooper 1967). The clinician should provide oral instructions, as well as printed cards, outlining these instructions to patients who are taking classic MAOIs.

In addition to the food interaction, drug interactions are extremely important (see next section, "Drug–Drug Interactions"). Each patient should be given a card indicating that he or she is taking an MAOI and instructions that the card should be carried at all times. A medical bracelet indicating that the wearer takes an MAOI is also a good idea.

DRUG–DRUG INTERACTIONS

The extensive inhibition of MAO enzymes by MAOIs raises the potential for a number of drug interactions (Table 18–4). Of particular importance, many over-the-counter medications can interact with MAOIs. These medications include cough syrups containing sympathomimetic agents, which in the presence of an MAOI can precipitate a hypertensive crisis.

TABLE 18–4. Drug interactions with monoamine oxidase inhibitors (MAOIs)

Drug	Interaction	Comment
Other MAOIs (e.g., furazolidone, pargyline, procarbazine)	Potentiation of side effects; convulsions possible	Allow at least 1 week before changing MAOI
Tricyclic antidepressants (TCAs) (e.g., maprotiline, bupropion)	Severe side effects, such as hypertension and convulsions, possible	Allow at least 2 weeks before changing MAOI; combinations have been used occasionally for refractory depression
Carbamazepine	Low possibility of interaction; similar to TCAs	Same as for TCAs
Cyclobenzaprine	Low possibility of interaction; similar to TCAs	Same as for TCAs
Selective serotonin reuptake inhibitors (SSRIs)	Serotonin syndrome	Avoid combinations; allow at least 2 weeks before changing MAOI and 5 weeks if switching from fluoxetine to MAOI
Stimulants (e.g., methylphenidate, dextroamphetamine)	Potential for increased blood pressure (hypertension)	Avoid combination
Buspirone	Potential for increased blood pressure (hypertension)	Avoid use; if used, monitor blood pressure
Meperidine	Severe, potentially fatal interaction possible (see text)	Avoid combination
Dextromethorphan	Reports of brief psychosis	Avoid high doses
Direct sympathomimetics (e.g., L-dopa)	Increased blood pressure	Avoid use, if possible; if they need to be used, use with caution
Indirect sympathomimetics	Hypertensive crisis possible	Avoid use
Oral hypoglycemics (e.g., insulin)	Worsening of hypoglycemia possible	Monitor blood sugar levels and adjust medications
Fenfluramine	Serotonin syndrome possible	Avoid use
L-Tryptophan	Serotonin syndrome possible	Avoid use

Another area of caution is the use of MAOIs in patients who need surgery. In this situation, interactions include those with narcotic drugs, especially meperidine. Meperidine administered with MAOIs can produce a syndrome characterized by coma, hyperpyrexia, and hypertension. This syndrome has been reported primarily with phenelzine; however, it has also been reported with tranylcypromine (Mendelson 1979; Stack et al. 1988). Stack et al. (1988) noted that this syndrome is

most likely to occur with meperidine and that it may be related to that drug's serotonergic properties. Similar reactions have not been reported to any significant extent with other narcotic analgesics such as morphine and codeine. In fact, many patients probably receive these medications without problems. Only a small fraction of patients may have this interaction, and it could reflect an idiosyncratic effect. In general, current opinion favors the use of morphine or fentanyl when intra- or postoperative narcotics are needed in patients taking MAOIs.

The issue of whether directly acting sympathomimetic amines interact with MAOIs is more controversial. Intravenous administration of sympathomimetic amines to patients receiving MAOIs does not provoke hypertension. When a bolus infusion of catecholamines is given to healthy volunteer subjects who have been taking phenelzine or tranylcypromine for 1 week, a potentiation of the pressor effect of phenylephrine occurs, but no clinically significant potentiation of cardiovascular effects of NE, epinephrine, or isoproterenol occurs (Wells 1989).

In general, direct sympathomimetic amine–MAOI interactions do not appear to produce significant cardiovascular problems. However, there is a low incidence of hypertensive episodes in the presence of indirect sympathomimetics. Ideally, these compounds should not be used in those patients who are receiving MAOIs. A direct-acting compound is preferable to an indirect-acting compound.

Caution should be exercised when using MAOIs in patients with pheochromocytoma and cardiovascular, cerebrovascular, and hepatic disease. Because phenelzine tablets contain gluten, they should not be given to patients with celiac disease.

SPECIFIC MONOAMINE OXIDASE INHIBITORS

Phenelzine

Phenelzine, a hydrazine derivative, is a potent MAOI and the best studied among the MAOIs.

Pharmacokinetics

Phenelzine is a substrate as well as an inhibitor of MAO, and major identified metabolites of phenelzine include phenylacetic acid and *p*-hydroxyphenylacetic acid. Phenelzine undergoes acetylation, and therefore drug levels are lower in fast acetylators than in slow acetylators. However, because phenelzine is an irreversible inhibitor, plasma concentrations are not relevant. The antidepressant effect, the degree of inhibition of MAO, and the amount of free phenelzine excreted in the urine are all significantly greater in slow acetylators than in fast acetylators (Baker et al. 1999).

Efficacy

Phenelzine is useful in the treatment of major depression, atypical depression, panic disorder, social phobia, and atypical facial pain (see section "Indications and Efficacy" presented earlier in this chapter).

Side Effects

The primary side effects of phenelzine are similar to those of other MAOIs. Hepatitis secondary to phenelzine may occur. This effect is quite rare (<1 in 30,000). The most difficult side effect, often leading to discontinuation, is postural hypotension.

Contraindications

The contraindications to phenelzine include known sensitivity to the drug, pheochromocytoma, congestive heart failure, and history of liver disease. (In addition, see sections "Dietary Interactions" and "Drug–Drug Interactions" presented earlier in this chapter.)

Isocarboxazid

Isocarboxazid is a hydrazine type of MAOI.

Pharmacokinetics

Isocarboxazid is rapidly absorbed from the gastrointestinal tract and is metabolized in the liver. It is primarily excreted as hippuric acid. Its half-life is of little interest because it is an irreversible MAOI. Chemically, isocarboxazid is 5-methyl-3-isoxazolecarboxylic acid 2-benzylhydrazide. Isocarboxazid is a colorless crystalline substance with very little taste.

Efficacy

Isocarboxazid is the least studied of the MAOIs. Its indications are similar to those of the other MAOIs.

Side Effects

The side effects of isocarboxazid are similar to those of phenelzine. Postural hypotension is the most common problem.

Contraindications

The contraindications to isocarboxazid are similar to those of phenelzine.

Tranylcypromine

Tranylcypromine, a nonhydrazine reversible MAOI, increases the concentration of NE, epinephrine, and 5-HT in the CNS. When tranylcypromine is discontinued, about 5 days are needed for recovery of MAO function. Tranylcypromine has a mild stimulant effect.

Pharmacokinetics

Limited data exist on pharmacokinetics. Tranylcypromine is excreted within 24 hours. The dynamic effect lasts for up to 5 days after withdrawal. There is considerable debate about whether it is metabolized to amphetamine; most studies in the literature indicate that this does not occur.

Efficacy

Tranylcypromine's indications are similar to those of other MAOIs (see section "Indications and Efficacy" presented earlier in this chapter).

Side Effects

The side effects of tranylcypromine are similar to those of other MAOIs. In addition, problems with physical dependence on tranylcypromine have been reported. Thus, withdrawal symptoms, such as anxiety, restlessness, depression, and headache, may occur. Syndrome of inappropriate antidiuretic hormone (SIADH) has been reported with tranylcypromine. Rare cases of toxic hepatitis have been reported. Tranylcypromine can lead to increased agitation, insomnia, and restlessness, compared with phenelzine.

Contraindications

The contraindications to tranylcypromine are the same as those for phenelzine. In addition, in view of the greater potential for hypertensive episodes, tranylcypromine should be used with particular caution in patients with cerebrovascular or cardiovascular disease.

Moclobemide

Moclobemide, a reversible inhibitor of MAO-A enzyme (Amrein et al. 1989), has a higher potency in vivo than in vitro. Therefore, it has been suggested that moclobemide is a prodrug and that it is metabolized to a form with higher affinity for MAO-A than the parent compound. After single- or repeated-dose moclobemide administration, the recovery of MAO-A activity is much shorter than that

seen with other MAOIs, including clorgyline, an irreversible inhibitor of MAO-A. One of the metabolites of moclobemide does inhibit MAO-B; however, this action is minimally significant in humans. When administered to rats, moclobemide increases the concentration of 5-HT, NE, epinephrine, and DA in rat brain (see Haefely et al. 1992). These effects are short-lasting, and they parallel the time course of MAO-A inhibition. In addition, unlike irreversible inhibitors, repeated administration does not increase the inhibition.

In animals, moclobemide only partially potentiates the blood pressor effect of oral tyramine. This is because it is a reversible inhibitor with a low affinity for the MAO isoenzymes and is easily displaced by the pressor amines ingested in food. On the basis of these studies, moclobemide is thought to be safer than irreversible MAOIs.

Pharmacokinetics

After oral administration of moclobemide, peak plasma concentrations are reached within 1 hour. The drug is about 50% bound to plasma proteins and is extensively metabolized; only 1% of the compound is excreted (unchanged) in the urine. The half-life of the compound is approximately 12 hours. Moclobemide is extensively metabolized; 95% of the administered dose is excreted in the urine. The metabolites are pharmacologically inactive. The presence of food reduces the rate (but not the extent) of moclobemide absorption.

Efficacy

Moclobemide has been studied in all types of depressive disorders (Gabelic and Kuhn 1990; Larsen et al. 1991; Rossel and Moll 1990). Controlled trials have found that it is superior to placebo. In addition, moclobemide has been found to be as effective as imipramine, desipramine, clomipramine, and amitriptyline in the treatment of depression. The dosage required is 300–600 mg/day.

Unlike the classic MAOIs, moclobemide has been found to be effective in treating both endogenous and nonendogenous depression. In addition, in combination with antipsychotics, the drug seems to be effective in treating psychotic depression (Amrein et al. 1989). Moclobemide has also been effective in treating bipolar endogenous depression.

Versiani et al. (1992) compared phenelzine, moclobemide, and placebo and reported that both phenelzine and moclobemide were superior to placebo in treating patients with social phobia. Given the efficacy of classic MAOIs in the treatment of other psychiatric disorders, such as bulimia, panic disorder, and PTSD, it is likely that patients with such disorders would respond to the reversible MAOIs. Additional trials of moclobemide are required to confirm its utility in other psychiatric disorders.

Side Effects

Nausea was the only side effect noted to be greater in patients taking moclobemide than in patients taking placebo. Thus, the profile of moclobemide seems to be ideal in that it causes few or no major side effects. Case reports have shown no toxicity after overdoses of up to 20 g (Amrein et al. 1989).

Dietary Interactions

Intravenous tyramine pressor tests indicate that a single dose of moclobemide increases tyramine sensitivity (Cusson et al. 1991). However, this increase is marginal, compared with the increase associated with other MAOIs. Under most conditions, there appears to be limited drug–food interaction. However, to minimize even mild tyramine pressor effects, it would be preferable to administer moclobemide after a meal rather than before it. In a study in which tyramine was administered in doses of up to 100 mg, inpatients pretreated with moclobemide had no significant changes in blood pressure. The drug also has minimal effect on cognitive performance and no effect on body weight or hematological parameters (Wesnes et al. 1989; Youdim et al. 1987).

Drug–Drug Interactions

Several studies have examined potential drug–drug interactions with moclobemide (Amrein et al. 1992). No drug interaction with lithium or in combination with TCAs has been reported. Moclobemide has also been combined with fluoxetine and other SSRIs with no significant interaction. No interactions with benzodiazepines or neuroleptics have been reported (Amrein et al. 1992). Parallel data suggest that moclobemide can potentiate the effects of meperidine; therefore, the narcotic–MAOI interaction may occur. Until proven otherwise, it would be prudent to avoid the combination of moclobemide with opiates like meperidine. A pharmacokinetic interaction has been observed with cimetidine that requires the reduction of the moclobemide dose because cimetidine reduces the clearance of moclobemide.

Selegiline Hydrochloride

Selegiline hydrochloride is an irreversible MAO-B inhibitor (Cesura and Pletscher 1992). Its primary use is in the treatment of Parkinson's disease, as an adjunct to L-dopa and carbidopa. The average dosage for Parkinson's disease is 5–10 mg/day. The exact mechanism of action of MAO B in Parkinson's disease is unknown (Gerlach et al. 1996; Hagan et al. 1997; Lyytinen et al. 1997).

Pharmacokinetics

Selegiline is metabolized to levoamphetamine, methamphetamine, and *N*-desmethylselegiline. Selegiline hydrochloride undergoes significant first-pass metabolism following oral administration. Transdermal delivery avoids the first-pass effect and provides greater levels of unchanged drug and reduced levels of metabolites compared with the oral regimen. The time to reach the peak is less than 1 hour. The elimination half-life of selegiline is about 1.5 hours. There is at least a threefold increase in the area under the curve (AUC) of selegiline with food (Mahmood 1997).

Efficacy

The efficacy of selegiline in treating depression has not been well studied. The few studies that have examined its utility have been equivocal. The dose required for treating depression may be much higher than that required to treat Parkinson's disease. Clinical experience suggests that dosages of 20–40 mg/day are needed. At these dosages, dietary interactions could occur. Early studies have reported that selegiline is of modest benefit in patients with Alzheimer's disease (Lawlor et al. 1997). Quitkin et al. (1984) showed that L-deprenyl was superior to 6 weeks of placebo administered to patients with depression in a separate double-blind study. Dosages of more than 10–20 mg/day were needed.

Side Effects

Selegiline has been found to have no adverse effects when combined with other antidepressants during treatment of depression in patients with Parkinson's disease. The few side effects that have been noted with selegiline include nausea, dizziness, and light-headedness. When the drug is abruptly discontinued, nausea, hallucinations, and confusion have been reported.

Dietary Interactions

Because MAO-B is not involved in the intestinal tyramine interaction, dietary interaction with selegiline (at low dosages, i.e., 5–10 mg/day) would probably be minimal; therefore, no drug interactions have been reported. An interaction between selegiline and narcotics has been reported and should be kept in mind.

Selegiline Transdermal System

The selegiline transdermal system (STS) was developed to overcome limitations of orally administered

MAOIs, particularly dietary tyramine restrictions. The system does not overcome drug–drug interactions. It bypasses the gut, thereby reducing drug–food interactions. The pharmacokinetic and pharmacodynamic properties promote the inhibition of MAO-A and MAO-B in the CNS while avoiding significant inhibition of intestinal and liver MAO-A enzymes. Three different strengths of Emsam patch are currently marketed: 20 mg/20 cm^2, 30 mg/30 cm^2, and 40 mg/40 cm^2. The three patch sizes deliver 24-hour doses of selegiline averaging 6 mg, 9 mg, and 12 mg, respectively. Use of the lowest-dosage Emsam 6-mg/24-hour patch does not call for dietary modification. A restricted "MAOI diet" is advised for the higher-dosage Emsam 9-mg/24-hour patch and the 12-mg/24-hour patch to avoid any risk of hypertensive crisis. Patients are strongly advised to follow these restrictions.

Pharmacokinetics

Following dermal application of the selegiline patch, 25%–30% of the selegiline content on average is delivered systemically over 24 hours. Consequently, the degree of drug absorption is one-third higher than the average amounts of 6–12 mg/24 hours. In comparison with oral dosing, transdermal dosing results in substantially higher exposure to selegiline and lower exposure to metabolites.

Efficacy

The efficacy of STS as a treatment for major depressive disorder was established in two placebo-controlled studies of 6 and 8 weeks' duration in adult outpatients with major depressive disorder. In both studies, patients were randomly assigned to double-blind treatment with drug patch or placebo. The 6-week trial showed that 6 mg/24 hours was significantly more effective than placebo, as assessed by scores on the 17-item Hamilton Rating Scale for Depression (Ham-D) (Amsterdam 2003). In an 8-week dosage titration trial, depressed patients receiving the drug patch (starting dose was 6 mg/24 hours, with possible increases to 9 mg/24 hours or 12 mg/24 hours based on clinical response) showed significant improvement compared with those receiving placebo on the primary outcome measure, the 28-item Ham-D total score (Feiger et al. 2006). In another trial, 322 patients meeting DSM-IV-TR (American Psychiatric Association 2000) criteria for major depressive disorder who had responded during an initial 10-week open-label treatment phase were randomly assigned either to continuation at the same dose or to placebo under double-blind conditions for observation of relapse. In this double-blind phase, patients receiving continued selegiline transdermal experienced a significantly longer time to relapse (Amsterdam and Bodkin 2006).

Drug–Drug Interactions

Potential drug interactions for STS are the same as for other MAOIs.

CONCLUSION

Various MAOIs have been shown to be effective in treating a wide variety of psychiatric disorders, including depression, panic disorder, social phobia, and PTSD. The classic MAOIs are currently used only rarely as first-line medication because of potential dietary interactions and other long-term side effects. The reversible inhibitors of MAO-A enzyme, such as moclobemide, which have fewer side effects and no dietary restrictions compared with classic MAOIs, are unlikely to be introduced in the United States. In fact, the risk–benefit ratio for these compounds is highly favorable, compared with other antidepressants. The MAO-B inhibitor selegiline is used to reduce the progression of Parkinson's disease. Its utility in treating other degenerative disorders is currently being assessed. The selegiline transdermal system reduces dietary interactions when used at low doses and is now approved for the treatment of major depression. New applications and a wider use of these compounds may be found in the near future.

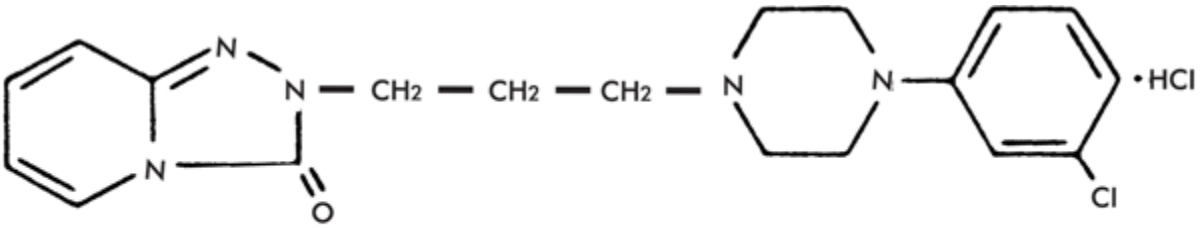
Chapter 19. Trazodone and Nefazodone

TRAZODONE AND NEFAZODONE: INTRODUCTION

Trazodone was among the earliest "second generation" antidepressants to become available for clinical use in the United States in the early 1980s. Its side-effect profile and potential toxicity were considerably different from and, in many instances preferable to, those of the original antidepressants (i.e., the monoamine oxidase inhibitors [MAOIs] and tricyclic antidepressants [TCAs]). Several years later, its pharmacological "cousin," nefazodone, joined the growing armamentarium of effective antidepressant medications.

TRAZODONE

History and Discovery



Trazodone was first synthesized in Italy about three decades ago, and clinical studies began in the United States in 1978. Trazodone was different from the conventional antidepressants that were available at that time in several ways. It was the first triazolopyridine derivative to be developed as an antidepressant. In addition, it was developed as an outgrowth of a specific hypothesis (i.e., that depression is caused by an imbalance in the brain mechanisms responsible for the emotional integration of adverse unpleasant experiences). For this reason, new animal models that measured the response to noxious stimuli or situations were used as screening tests for developing the drug. In fact, trazodone is inactive in classic antidepressant screening tests, such as the reserpine model, the potentiation of yohimbine toxicity, and the behavioral despair/forced swim paradigm, yet it inhibits painful and conditioned emotional responses (Silvestrini 1980). Trazodone shares with the phenothiazines the ability to suppress self-stimulation behavior and amphetamine effects, and it produces substantial blockade of α-adrenergic receptors. In sharp contrast to most other antidepressants available at the time of its development, trazodone showed minimal effects on muscarinic cholinergic receptors.

In 1982, trazodone was introduced for clinical use in the United States under the brand name Desyrel. It quickly became a widely prescribed medication, capturing up to one-third of the American market. More recently, the availability of the extremely popular selective serotonin reuptake inhibitors (SSRIs) has led to a decline in trazodone use. The medication is now available in generic formulation.

Structure–Activity Relations

Trazodone is chemically unrelated to other antidepressant drugs, although it does resemble some of the side-chain components of TCAs and the phenothiazines. Its structure (Figure 19–1) includes a triazole moiety that may be linked to its antidepressant activity.

Pharmacological Profile

The effects of trazodone on serotonergic systems are complex. Trazodone is a relatively weak SSRI, compared with the more potent SSRIs such as fluoxetine or paroxetine. However, it is relatively *specific* for serotonin (5-HT) uptake inhibition, with minimal effects on norepinephrine (NE) or dopamine reuptake (Hyttel 1982). In the rat, systemic administration of trazodone leads to fivefold increases in extracellular 5-HT concentrations in the frontal cortex, which can be blocked by pretreatment with fluoxetine. Direct administration into the frontal cortex via reverse dialysis also elicits increases in extracellular 5-HT levels that are reduced by local perfusion of ketanserin. Thus, trazodone appears to increase extracellular 5-HT concentrations through a combination of mechanisms involving the 5-HT transporter (5-HTT) and the serotonin$_{2A/2C}$ (5-HT$_{2A/2C}$) receptors (Pazzagli et al. 1999). In addition, trazodone has some 5-HT receptor antagonist activity, particularly at serotonin$_{1A}$ (5-HT$_{1A}$), serotonin$_{1C}$ (5-HT$_{1C}$), and serotonin$_2$ (5-HT$_2$) receptor subtypes (Haria et al. 1994). Furthermore, its active metabolite, *m*-chlorophenylpiperazine (m-CPP), is a potent direct 5-HT agonist. Thus, trazodone can be viewed as a mixed serotonergic agonist–antagonist, with the relative amount of m-CPP accumulation affecting the relative degree of the predominant agonist activity.

In vivo, trazodone is virtually devoid of anticholinergic activity, and in clinical studies, the incidence of anticholinergic side effects is similar to that seen with placebo. Trazodone is a relatively weak blocker of presynaptic α_2-adrenergic receptors and a relatively potent antagonist of postsynaptic α_1-adrenergic receptors. The latter property probably accounts for its propensity to cause orthostatic hypotension. Trazodone has moderate antihistaminergic (histamine$_1$ [H$_1$] receptor) activity.

Pharmacokinetics and Disposition

Trazodone is well absorbed after oral administration, with peak blood levels occurring about 1 hour after dosing when the drug is taken on an empty stomach and about 2 hours after dosing when the drug is taken with food. Trazodone is 89%–95% bound to plasma protein. Elimination appears to be biphasic, consisting of an initial alpha phase followed by a slower beta phase, with half-lives of 3–6 and 5–9 hours, respectively. Bioavailability is not influenced by age or by food intake. Gender differences are inconsistent.

Trazodone undergoes extensive hepatic metabolism, including hydroxylation, splitting at the pyridine ring, oxidation, and *N*-oxidation. Less than 1% of the drug is excreted unchanged in feces and urine. The active metabolite m-CPP is cleared more slowly than the parent compound (4- to 14-hour half-life) and reaches higher concentrations in the brain than in plasma (Caccia et al. 1981). The cytochrome P450 (CYP) 2D6 and 3A microsomal enzyme systems also appear to play a role in trazodone metabolism. CYP3A inhibitors (e.g., ketoconazole, ritonavir, indinavir) inhibit trazodone clearance (see Zalma et al. 2000), and ketoconazole inhibits m-CPP formation (Rotzinger et al. 1998).

The relation between steady-state blood levels and clinical response to trazodone is unclear. In a study involving geriatric patients, plasma concentrations of trazodone were lower in responders compared with nonresponders (Spar 1987). However, this study was limited by the lack of a

fixed-dose design (increasing the chances that patients who were destined to be nonresponders would have continued dose increases, yielding relatively higher plasma levels) and a small sample size. Another study of geriatric patients found a positive relation between steady-state trazodone plasma concentrations and clinical response in a sample of 11 subjects (Monteleone and Gnocchi 1990).

Mechanism of Action

The ultimate mechanism of action of trazodone remains unclear. Although the drug is often referred to as a 5-HT reuptake inhibitor, such labeling overlooks the complexity of its effects on this neurotransmitter system. Binding studies confirm that trazodone has relative selectivity for 5-HT reuptake sites (Hyttel 1982); however, in vivo, it blocks the head twitch response induced by classic 5-HT agonists in animals. The potent 5-HT agonist properties of trazodone's major metabolite, m-CPP, may play a role in the mechanism of action of the parent compound. Trazodone, unlike the vast majority of antidepressants, does not produce downregulation of β-adrenergic receptors in rat cortex (Sulser 1983).

Indications and Efficacy

The primary indication for trazodone is the treatment of major depression. In a review of the double-blind studies published after the release of trazodone in this country, Schatzberg (1987) found the therapeutic efficacy of trazodone to be similar to that of TCAs in patients with either endogenous or nonendogenous depression. A review of the European literature by Lader (1987) yielded similar findings: data from open and double-blind trials suggest that the antidepressant efficacy of trazodone is comparable to that of amitriptyline, doxepin, and mianserin. Also, trazodone showed anxiolytic properties, low cardiotoxicity, and relatively mild side effects in the European studies.

Questions have been raised about the effectiveness of trazodone in treating severely ill patients, especially those with prominent psychomotor retardation (Klein and Muller 1985). Shopsin et al. (1981) pointed out that in several unpublished double-blind, controlled studies, the rates of clinical response to trazodone were low (i.e., 10%–20%). Lader (1987) acknowledged that the numbers of patients with psychomotor retardation in the reported studies are too small to resolve the controversy regarding the efficacy of trazodone in this population.

The performance of trazodone, in direct comparisons with other second-generation antidepressants, has been mixed. In a double-blind, placebo-controlled comparison with venlafaxine, the final response rates were 55% for placebo, 60% for trazodone, and 72% for venlafaxine. Trazodone was more effective than venlafaxine in ameliorating sleep disturbances and was associated with the most dizziness and somnolence (Cunningham et al. 1994). In a double-blind comparison, response rates for trazodone and bupropion were 46% and 58%, respectively (see Weisler et al. 1994). In a double-blind study of 200 hospitalized patients with moderate to severe major depressive episode, mirtazapine yielded greater reductions in depression ratings than did trazodone (van Moffaert et al. 1995).

Because trazodone has minimal anticholinergic activity, it was especially welcomed as a treatment for geriatric patients with depression when it first became available. Three double-blind studies reported that trazodone has antidepressant efficacy similar to that of other antidepressants in geriatric patients (Gerner 1987). However, a side effect of trazodone, orthostatic hypotension, which may cause dizziness and increase the risk of falls, can have devastating consequences in elderly patients; thus, this side effect, along with sedation, often makes trazodone less acceptable in this population, compared with newer compounds that share its lack of anticholinergic activity but not the rest of its side-effect profile. Still, trazodone is often helpful for geriatric patients with depression who have severe agitation and insomnia. A recent survey of British geropsychiatrists identified trazodone as one of their most popular adjuncts or alternatives to atypical antipsychotics in the management of

behavioral symptoms in the elderly (Condren and Cooney 2001). A randomized, controlled trial found that trazodone, haloperidol, behavioral management techniques, and placebo each produced comparable modest reductions in agitation associated with Alzheimer's disease (Teri et al. 2001). Another double-blind study reported comparable therapeutic effects for trazodone and haloperidol in the treatment of dementia-associated agitated behaviors, with more common adverse effects in the latter group (Sultzer et al. 1997). A recent Cochrane Database review found insufficient evidence to support trazodone as a treatment for the behavioral and psychological symptoms of dementia, although the review could not conclude that trazodone was ineffective, given the limited number of eligible studies (Martinon-Torres et al. 2004).

Trazodone has also been reported to have antianxiety properties. In a randomized, double-blind, placebo-controlled trial, the anxiolytic efficacy of trazodone was comparable to that of diazepam in weeks 3–8 of treatment for generalized anxiety disorder, although patients treated with diazepam had greater improvement during the first 2 weeks of treatment (Rickels et al. 1993). Early case reports had indicated that trazodone is associated with improvement in obsessive-compulsive disorder, but a double-blind, placebo-controlled study found that trazodone lacked antiobsessional effects (Pigott et al. 1992).

Many clinicians use low-dose trazodone as an alternative to benzodiazepines for the treatment of insomnia. Two recent reviews found that trazodone is the second most prescribed agent for insomnia, even though there is minimal evidence to support its use for this indication (Mendelson 2005; Rosenberg 2006). Mendelson (2005) noted that there are few data to support trazodone's use in primary insomnia, because most studies have been limited to patients with depression. In addition, the available literature is characterized by small sample sizes, limited control groups, and weak statistical analyses. Rosenberg (2006) arrived at very similar conclusions. Controlled trials have confirmed trazodone's efficacy (at doses of 50–100 mg) in treating insomnia that occurs as a side effect of some antidepressants (Nierenberg et al. 1994). A retrospective analysis at a Department of Veterans Affairs (VA) medical center found that approximately 24% of patients receiving trazodone were taking other primary antidepressants (Clark and Alexander 2000). Another VA study of patients with posttraumatic stress disorder (PTSD) found that of those patients who were able to tolerate trazodone (60 of 72 patients), 92% reported that it improved sleep onset and 78% reported that it improved sleep maintenance (Warner et al. 2001).

Trazodone has been investigated as a treatment for adjustment disorders in medically ill populations. A randomized, double-blind study found a trend toward greater efficacy in trazodone, compared with clorazepate, in the management of adjustment disorders in patients with breast cancer (Razavi et al. 1999). A similar trend was noted in a study of adjustment disorders in patients who tested positive for HIV (DeWit et al. 1999).

A handful of reports have described the use of trazodone in the treatment of bulimia nervosa, including a well-designed placebo-controlled trial that found trazodone to be superior to placebo in reducing the frequency of episodes of binge eating and vomiting (Hudson et al. 1989). In addition, trazodone has been found to be effective in the treatment of erectile dysfunction in some (e.g., Lance et al. 1995), but not all (e.g., Costabile and Spevak 1999), studies.

Whether prescribed as an antidepressant or a hypnotic, trazodone should always be initiated at a low dose and increased gradually, based on clinical response and tolerance to side effects. For the treatment of a major depressive episode, the suggested initial dosage is 150 mg/day, with increases of 50-mg increments every 3–4 days. Doses may be divided, although many patients prefer bedtime dosing because of the sedating effects. The maximum dosage recommended for outpatients is 400 mg/day, although for inpatients with more severe depression, dosages up to 600 mg/day have been used. When trazodone is prescribed as a hypnotic agent, the usual dose is 50 mg at bedtime, although some patients may require as little as 25 mg or as much as 200–300 mg.

Side Effects and Toxicology

Because of its lack of anticholinergic side effects, trazodone is especially useful in situations in which antimuscarinic effects are particularly problematic (e.g., in patients with prostatic hypertrophy, closed-angle glaucoma, or severe constipation). Trazodone's propensity to cause sedation is a dual-edged sword. For many patients, the relief from agitation, anxiety, and insomnia can be rapid; for other patients, including those individuals with considerable psychomotor retardation and feelings of low energy, therapeutic doses of trazodone may not be tolerable because of sedation.

Trazodone elicits orthostatic hypotension in some patients, probably as a consequence of α_1-adrenergic receptor blockade. Trazodone-related syncope in the elderly has been described in the literature (Nambudiri et al. 1989). A study of nursing home residents, however, found no increased rate of falls during the initiation of trazodone therapy, compared with tricyclic or SSRI therapy (Thapa et al. 1998). By contrast, trazodone was found to be among the top three medications associated with orthostatic hypotension in patients attending a VA geriatric clinic (Poon and Braun 2005). Case reports have noted cardiac arrhythmias emerging in relation to trazodone treatment, both in patients with preexisting mitral valve prolapse and in patients with negative personal and family histories of cardiac disease (see Janowsky et al. 1983; Lippman et al. 1983; Winkler et al. 2006).

A relatively rare, but dramatic, side effect associated with trazodone is priapism. More than 200 cases have been reported (Thompson et al. 1990), and the manufacturer estimates that the incidence of any abnormal erectile function is approximately 1 in 6,000 male patients treated with trazodone. The risk for this side effect appears to be greatest during the first month of treatment at low dosages (i.e., <150 mg/day). Early recognition of any abnormal erectile function, including prolonged or inappropriate erections, is important and should prompt discontinuation of trazodone treatment. Clinical reports have also described trazodone-associated psychosexual side effects in women, including increased libido (Gatrell 1986), priapism of the clitoris (Pescatori et al. 1993), and spontaneous orgasms (Purcell and Ghurye 1995).

Mania has been observed in association with trazodone treatment (as with nearly all antidepressants), including in patients with bipolar disorder as well as in patients with previous diagnoses of unipolar depression. Terao (1993) found that the switch process occurs more rapidly in trazodone-treated patients than in fluoxetine-treated patients.

Trazodone appears to be *relatively* safer than TCAs, MAOIs, and a few of the other second-generation antidepressants in overdose situations, especially when it is the only agent taken. Fatalities are rare, and uneventful recoveries have been reported after ingestion of doses as high as 6,000–9,200 mg (Ayd 1984). In one report, 9 of 294 cases of overdose were fatal, and all 9 patients had also taken other central nervous system (CNS) depressants (Gamble and Peterson 1986). When trazodone overdoses occur, clinicians should carefully monitor for hypotension, a potentially serious toxic effect. In a report of a fatal trazodone overdose, torsades de pointes and complete atrioventricular block developed, along with subsequent multiple organ failure, with a trazodone plasma concentration of 25.4 μg/mL on admission (de Meester et al. 2001).

Drug–Drug Interactions

Trazodone can potentiate the effects of other CNS depressants. Patients should be warned about increased drowsiness and sedation when trazodone is combined with other CNS depressants, including alcohol.

The combination of trazodone with an MAOI, as with other antidepressants, should be handled with great caution, although there are case reports of the successful combination of trazodone with an MAOI (Zimmer et al. 1984). Development of the serotonin syndrome has been associated with the combination of trazodone with other proserotonergic agents, including an MAOI (plus

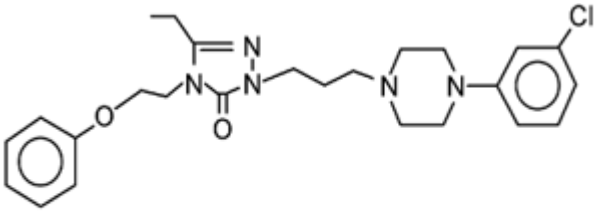
methylphenidate) (Bodner et al. 1995), buspirone (Goldberg and Huk 1992), paroxetine (Reeves and Bullen 1995), nefazodone (Margolese and Chouinard 2000), and lithium plus amitriptyline (Nisijima et al. 1996). The addition of fluoxetine to trazodone treatment led to increases in plasma concentrations of both trazodone and m-CPP (Maes et al. 1997).

Trazodone inhibits the antihypertensive effects of clonidine (Georgotas et al. 1982). On the other hand, trazodone itself can cause hypotension, especially orthostatic hypotension, and the manufacturer states in the package insert for Desyrel that concomitant administration of trazodone with antihypertensive therapy may require a reduction in the dose of the antihypertensive agent.

Drug–drug interactions with anticoagulants are of great concern, given the potentially serious consequences of too much or too little anticoagulant effect. Three clinically significant cases of suspected trazodone–warfarin interactions were described in a retrospective chart review (Small and Giamonna 2000). The initiation of trazodone treatment was associated with a subsequent decrease in prothrombin time (PT) and international normalized ratio (INR) that could not be explained by other factors. Conversely, in a patient who stopped trazodone, PT and INR increased.

Recently, combined administration of the antibiotic linezolid and trazodone has been associated with emergence of serotonin syndrome (Bergeron et al. 2005).

NEFAZODONE



History and Discovery

Trazodone's sedative properties and association with orthostatic hypotension eventually inspired an effort to discover a modified molecule, utilizing receptor-binding techniques, which would possess a more desirable pharmacological profile. This led to the development of nefazodone (Taylor et al. 1986), which became available for clinical use in the United States in 1994. Nefazodone can be considered a member of the trazodone family because they share a common active metabolite.

Structure–Activity Relations

Nefazodone is a phenylpiperazine compound. Its chemical structure, shown in Figure 19–2, is similar to that of trazodone.

FIGURE 19–2. Chemical structure of nefazodone.

Copyright © American Psychiatric Publishing, Inc., or American Psychiatric Association, unless otherwise indicated in figure legend. All rights reserved.

Pharmacological Profile

Nefazodone is a 5-HT_2 receptor antagonist and a weak inhibitor of 5-HT and NE reuptake. It has little affinity for α_2-adrenergic, β-adrenergic, or 5-HT_{1A} receptors, and its affinity for the α_1-adrenergic receptor is less than that of trazodone (Eison et al. 1990). Nefazodone is inactive at most other receptor-binding sites, including H_1, muscarinic, dopamine, benzodiazepine, γ-aminobutyric acid (GABA), μ opiate, and calcium channel receptors (Taylor et al. 1986).

Nefazodone demonstrates several of the classic preclinical characteristics of antidepressants. It prevents reserpine-induced ptosis in mice and reverses learned helplessness in rats. The effects of

nefazodone on electrophysiological measures of serotonergic systems are similar to those of many other effective antidepressants (Blier et al. 1990). In humans, nefazodone does not suppress rapid eye movement (REM) sleep, in contrast to most other antidepressants (Sharpley et al. 1996).

Pharmacokinetics and Disposition

Nefazodone is rapidly and completely absorbed and is then extensively metabolized, resulting in a low (about 20%) and variable absolute bioavailability. The plasma half-life is only 2–4 hours. Nefazodone has three active metabolites: desethyl hydroxynefazodone (triazole dione), hydroxynefazodone, and m-CPP. Triazole dione is a specific 5-HT_2 antagonist with weaker affinity for that receptor than the parent compound and no appreciable effects on 5-HT reuptake. With a plasma half-life of 18 hours, triazole dione predominates in the plasma, occurring at concentrations approaching four times that of the parent compound. Hydroxynefazodone has similar affinities for the 5-HT_2 receptor and 5-HT reuptake site as the parent compound. Its plasma half-life is between 1.5 and 4 hours, and at steady state, plasma concentrations are approximately 40% of the parent compound. m-CPP is a direct agonist at the 5-HT_1, 5-HT_2, and serotonin3 (5-HT_3) receptors, with one order of magnitude higher affinity for 5-HT_{2C} receptors. m-CPP has a plasma half-life of 4–8 hours, and its plasma concentrations are only 7% of those seen with the parent compound (DeVane et al. 2002; Eison et al. 1990; Mayol et al. 1994).

In rodent studies, there are striking differences in the brain-to-blood partition of nefazodone and its metabolites. The ratios of m-CPP to nefazodone concentrations in the brain are 47:1 and 10:1 in the mouse and rat, respectively. Brain concentrations of hydroxynefazodone in the rat are less than 10% of those in plasma, suggesting very poor blood–brain barrier penetration. Thus, despite its relatively lower plasma concentrations, m-CPP has substantial presence in the brain, whereas the in vivo activity of hydroxynefazodone may be mostly the result of its biotransformation to m-CPP (Nacca et al. 1998).

Nefazodone has nonlinear kinetics, which result in greater than proportional mean plasma concentrations with higher doses. Similar kinetics for nefazodone and hydroxynefazodone are seen in poor and extensive metabolizers, whereas m-CPP is eliminated more slowly by poor metabolizers. Nefazodone is extensively (99%) but loosely protein bound. It does not displace chlorpromazine, desipramine, diazepam, diphenylhydantoin, lidocaine, prazosin, propranolol, verapamil, or warfarin (Bristol-Myers Squibb Pharmaceutical Research Institute, data on file, June 1994). In patients with hepatic cirrhosis, single-dose nefazodone and hydroxynefazodone levels are about twice as high as in healthy volunteers, but the difference decreases to approximately 25% at steady state. Exposure to m-CPP is about two- to threefold greater in patients with cirrhosis, and exposure to triazole dione is similar after a single dose and at steady state (Barbhaiya et al. 1995).

Mechanism of Action

The mechanism of action of nefazodone is poorly understood. The manufacturer indicates that nefazodone antagonizes 5-HT_2 receptors and also inhibits neuronal uptake of both 5-HT and NE (Serzone [package insert] 2002). Several reviews refer to nefazodone as a "dual acting" antidepressant, suggesting that it enhances both serotonergic and noradrenergic neurotransmission via uptake blockade. Although it is accurate to characterize nefazodone as having similar effects on the 5-HTT and NE transporter, such a description is potentially misleading. Nefazodone's inhibition of NE reuptake is weaker than that of the SSRI fluoxetine, and approximately three orders of magnitude weaker than what is seen with conventional NE reuptake inhibitors, such as desipramine. Furthermore, nefazodone's inhibition of 5-HT reuptake is nearly identical to that of desipramine and more than 100-fold less than that of fluoxetine (Bolden-Watson and Richelson 1993). Thus, the "dual action" of nefazodone refers to minimal, albeit equal, effects on 5-HT and NE reuptake inhibition.

In a study examining the clinical psychobiological effects of nefazodone and SSRIs in patients with

depression, the latter treatment yielded decreases from mean baseline platelet 5-HT content that were significantly greater than the effects of nefazodone, suggesting that therapeutic doses of nefazodone do not cause sustained 5-HT uptake inhibition at the platelet 5-HTT (Narayan et al. 1998). The active metabolite m-CCP, which appears to predominate in the brain because of greater penetration of the blood–brain barrier (for details, see Nacca et al. 1998), may play an important role in the mechanism of action.

Indications and Efficacy

In three of four Phase III imipramine- and placebo-controlled studies, nefazodone was found to be an effective antidepressant with similar efficacy to imipramine; in one of these studies, neither active drug had significantly greater efficacy than did placebo. The incidence of premature treatment discontinuation and side effects was higher for the imipramine group than for the nefazodone treatment group (Rickels et al. 1995). In a double-blind study without a placebo control group, there was no significant difference in the clinical responses to nefazodone and sertraline in outpatients with depression, and sertraline had negative effects on sexual function and satisfaction (Feiger et al. 1996). A similar study in outpatients with moderate to severe depression found no difference between nefazodone and paroxetine in treatment outcome or discontinuation because of adverse events (Baldwin et al. 1996). Hospitalized patients with severe major depression achieved higher response rates to nefazodone, compared with placebo (Feighner et al. 1998). In contrast, a European study of patients with moderate to severe major depression reported that the efficacy of amitriptyline (50–200 mg/day) was clearly superior to that of nefazodone (100–400 mg/day) (Ansseau et al. 1994). In one of the first studies to include psychotherapy, Keller et al. (2000) compared nefazodone, cognitive-behavioral therapy (CBT), and a combination of these two treatments in a double-blind study of patients with chronic major depressive disorder. Each monotherapy yielded a response rate of 48%, whereas the combined treatment had a greater efficacy (73%). When patients who failed to respond to 12 weeks of treatment with either nefazodone or cognitive-behavioral analysis system psychotherapy are then switched to the other treatment, significant symptom improvement is achieved (Schatzberg et al. 2005). Nefazodone has also been shown to be effective in the continuation phase of treatment in double-blind studies with and without placebo controls (Anton et al. 1994; Baldwin et al. 2001; Feiger et al. 1999).

The usual starting dosage of nefazodone, as recommended by the manufacturer, is 200 mg/day in two divided doses. The suggested dosage range is 300–600 mg/day. Increases should be in increments of 100–200 mg/day at weekly intervals. The manufacturer points out that the starting dosage in elderly or debilitated patients should be lowered to 100 mg/day, again taken in two divided doses, and the rate of titration in these patient populations should be adjusted accordingly (Serzone [package insert] 2002). In a recent review expanding on this guideline, Zajecka et al. (2002) reported that in studies comparing low-dosage (50–250 mg/day) and high-dosage (100–500 mg/day) nefazodone, better clinical response was obtained in the latter group, and the mean effective dosage ranged from 375 to 460 mg/day. A lower starting dose should be considered when switching to nefazodone from an SSRI if a full washout has not been completed. The authors also cite data suggesting that once-daily bedtime dosing is safe, well tolerated, and effective (Zajecka et al. 2002).

Nefazodone has also been studied in other specific patient populations, including patients with substance abuse disorders. In a double-blind, placebo-controlled study, nefazodone was found to be safe and effective in the treatment of depression in patients with alcohol dependence, although it did not add any advantage over psychoeducational group intervention in terms of drinking outcomes (Roy-Byrne et al. 2000). A double-blind, controlled study found that nefazodone was not efficacious for the treatment of alcohol dependence (Kranzler et al. 2000). A recent randomized, placebo-controlled, double-blind multicenter study compared nefazodone versus placebo and CBT versus nondirective group counseling (GC) for relapse prevention in alcohol dependence. Two hundred

forty-two male patients with alcohol dependence received either nefazodone plus GC or CBT or placebo plus GC or CBT. There were no differences between the four groups in cumulative days of abstinence or amount of alcohol consumed during specified time periods during the initial 12-week study phase. After 1 year, the only significant difference between the groups was higher alcohol consumption in the nefazodone plus GC group, raising concerns that nefazodone may potentially increase the risk of relapse (Wetzel et al. 2004). A 10-week randomized, double-blind, placebo-controlled trial found no difference between nefazodone and placebo in the treatment of inhaled cocaine dependence (Passos et al. 2005). An 8-week double-blind, placebo-controlled trial of nefazodone in patients with cocaine dependence and comorbid depressive symptoms found equivalent improvements in self-reported cocaine use, psychosocial functioning, and mood in the nefazodone and placebo treatment groups (Ciraulo et al. 2005).

A 1998 open-label study found nefazodone to be effective in the treatment of social phobia (Worthington et al. 1998), but a more recent randomized, double-blind trial in 105 patients with generalized social phobia found no difference between nefazodone and placebo on the primary outcome measures (van Ameringen et al. 2007). Open-label studies with relatively small sample sizes have described the efficacy of nefazodone in the treatment of PTSD (Hidalgo et al. 1999), panic disorder (Bystritsky et al. 1999), generalized anxiety disorder (Hedges et al. 1996), chronic fatigue syndrome (Goodnick and Jorge 1999), chronic daily headache prophylaxis (Saper et al. 2001), depression in HIV-seropositive outpatients (Elliot et al. 1999), and seasonal affective disorder in women (Shen et al. 2005). A few open-label reports described the efficacy of nefazodone in the treatment of late luteal phase dysphoric disorder; however, a double-blind, controlled study reported no significant difference compared with placebo (Landen et al. 2001).

Side Effects and Toxicology

Nefazodone has been found to be safe and well tolerated in clinical trials that included approximately 2,250 patients. Side effects that occur more frequently in patients who receive nefazodone, compared with placebo, include dizziness, asthenia, dry mouth, nausea, and constipation. There was no evidence of cardiac dysfunction or cardiotoxicity in a careful review of more than 2,000 patients. Nefazodone modestly reduced resting pulse rate and supine blood pressure, but orthostatic hypotension was rare (Fontaine 1993).

Preskorn (1995) found that the total cumulative incidence of treatment-emergent adverse effects for nefazodone was lower than that of imipramine or fluoxetine. The most common placebo-adjusted adverse effects associated with nefazodone were dry mouth (7.5%), somnolence (5.8%), dizziness (5.6%), nausea (5.5%), constipation (3.3%), blurred vision (3.2%), and postural hypotension (2.6%). In the premarketing clinical trials, based on experience with approximately 3,500 patients, the rate of discontinuation due to adverse events for nefazodone was lower than that for imipramine and was comparable to that of fluoxetine (Robinson et al. 1996).

There are several reported cases of nefazodone-induced liver failure, including some in which there was irreversible damage (Aranda-Michel et al. 1999; Lucena et al. 1999; Schirren and Baretton 2000). The manufacturer issued a black box warning in the package insert, which describes a reported rate of life-threatening liver failure in this country of 1 per 250,000–300,000 patient-years of nefazodone treatment. Recommendations include avoiding the initiation of nefazodone treatment in patients with active liver disease or elevated baseline serum transaminases (because preexisting abnormalities can complicate patient monitoring); advising patients to be alert for signs and symptoms of liver dysfunction and to report any such occurrences to their doctor immediately; and discontinuing treatment if clinical signs or symptoms suggest liver failure. Any patient who develops evidence of liver damage, such as serum aspartate aminotransferase (AST) or alanine aminotransferase (ALT) levels that are three times greater than the upper limit of normal, while taking nefazodone should have the medication withdrawn and should never be reexposed.

Nefazodone appears to have advantages over SSRIs in terms of treatment-associated sexual dysfunction. An open-label multicenter prospective study of 1,022 patients with previously normal sexual function found substantially higher rates of treatment-associated sexual dysfunction with SSRIs (ranging from 58% to 73%), compared with nefazodone (8%) (Montejo et al. 2001). In a study of 105 patients with depression who had developed adverse sexual side effects attributable to sertraline, random double-blind assignment to either nefazodone or sertraline found significantly lower rates of reemergent sexual dysfunction with nefazodone (26%), compared with sertraline (76%), and the former group was more satisfied with sexual functioning than the latter group (Ferguson et al. 2001). In a recent cross-sectional study of more than 6,000 outpatients, nefazodone and bupropion were found to be associated with lower risk for sexual dysfunction, compared with SSRIs, mirtazapine, and venlafaxine (Clayton et al. 2002).

In a recent review of 1,338 humans with exposure to nefazodone poisoning, there were no reported deaths, and in the 45 cases for which estimated doses were available, no dose–response relationship emerged. The most common findings in the review were drowsiness, nausea, and dizziness. The most common serious clinical effect was hypotension, reported in 1.6% of cases. No patients required intubation, mechanical ventilation, or vasopressors, and this analysis suggests that nefazodone appears to have low toxicity in overdose situations (Benson et al. 2000).

Other rare nefazodone side effects have been described. An unusual visual side effect, akinetopsia (characterized by the inability to perceive motion in a normal, smooth fashion), as well as persistent strobelike images and visual trails behind moving objects, has been reported (Horton and Trobe 1999). A case report of nefazodone-induced mania supports the popular clinical opinion that probably all effective antidepressants can stimulate the switch process (Jeffries and Al-Jeshi 1995). There is a single case report of nefazodone-induced clitoral priapism lasting 3 days (Brodie-Meijer et al. 1999).

Drug–Drug Interactions

The manufacturer of triazolam warns that its concurrent use with nefazodone is contraindicated because of nefazodone's significant inhibition of oxidative metabolism mediated by CYP3A. Increases in the plasma concentration of digoxin occur with concurrent nefazodone administration, and although the increases are relatively modest, the combined administration of these two drugs should be avoided, in light of the narrow therapeutic index for digoxin. Nefazodone increases the plasma concentrations of terfenadine and loratadine (with associated QTc prolongation), carbamazepine (Abernethy et al. 2001; Laroudie et al. 2000), and cyclosporin (Wright et al. 1999). No significant pharmacokinetic or pharmacodynamic interactions have been noted between nefazodone and lorazepam, lithium, alcohol, cimetidine, propranolol, warfarin, or theophylline (Greene and Barbhaiya 1997).

CONCLUSION

Trazodone, one of the first second-generation antidepressants, and its pharmacological "cousin," nefazodone, do not readily fit within the conventional classifications of antidepressants. Do any common themes link these two "miscellaneous" medications?

In a way, trazodone and nefazodone (as well as bupropion and the tertiary-amine TCAs) remind us of the potential importance of metabolites in the clinical profile of pharmacological agents. m-CPP, the shared active metabolite of trazodone and nefazodone, may play a role in their mechanisms of action. Future research should clarify the specific role of this metabolite and its potential utility in therapeutic blood level monitoring.

Another theme is the important advantage for clinicians in understanding the basic pharmacology of a drug. Many side effects can be understood, or even predicted, on the basis of the pharmacological profiles of a medication. Thus, the propensity of trazodone to evoke orthostatic hypotension makes

sense in light of its effects on α-adrenergic receptors.

A review of trazodone also points out that "side effects" can potentially be exploited in the service of helping patients with conditions that are outside the realm of a drug's initial indication. The sedative properties of trazodone have led to its use in treating both primary and secondary insomnia (even in the absence of a strong evidence base to support this indication). The relatively rare side effect of priapism sparked several clinical studies in patients with erectile dysfunction, although the results to date are mixed. Thus, when thinking about side effects, one should consider the adage "One man's ceiling is another man's floor"; a clinical effect of a medication that is troubling to certain patients might potentially find use in treating targeted symptoms of other conditions.

Finally, each novel antidepressant adds to our available tools for the treatment of depression. Although we do not have a "perfect" antidepressant therapy that is safe and effective for all patients, novel compounds provide clinicians with additional options and flexibility in selecting the best available approach for each individual patient.

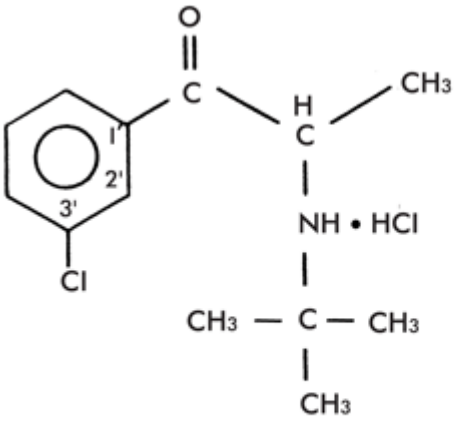
Chapter 20. Bupropion

HISTORY AND DISCOVERY

Bupropion was discovered more than 40 years ago when investigators were searching for an antidepressant with a novel mechanism of action and safer side-effect profile. Synthesized in 1966, this unique compound, different from tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs), was found to have antidepressant activity in animal models that are predictive of antidepressant activity in humans (Soroko and Maxwell 1983). Bupropion was discovered to have minimal sympathomimetic and anticholinergic side effects and a safer pharmacological and biochemical profile in comparison with other antidepressants. Although both bupropion and selective serotonin reuptake inhibitors (SSRIs) were developed with similar goals in mind, their mechanisms of action are unique (Hudziak and Rettew 2004; Soroko and Maxwell 1983). Bupropion is classified as an aminoketone antidepressant (Mehta 1983). Its mechanism of action is thought to be via dual inhibition of norepinephrine and dopamine reuptake (NDRI) without clinically significant serotonin reuptake inhibition (Horst and Preskorn 1998; Stahl et al. 2004). Both bupropion and SSRIs appear to be equally efficacious in the treatment of major depression (Feighner et al. 1991). The sustained-release (bupropion SR) formulation, approved in 1996, has also proved to be significantly better than placebo in preventing depression relapse (Weihs et al. 2002). Bupropion's tolerability is superior to that of SSRIs, with minimal effects on weight, less sedation, minimal withdrawal symptoms upon discontinuation, and fewer or no sexual side effects (Thase et al. 2005).

Besides treatment of major depression, bupropion has proven effective across a wide range of depressive conditions, subtypes, and comorbidities (Clayton 2007). These include major depression with concomitant anxiety, depression in the elderly, smoking cessation, attention-deficit/hyperactivity disorder (ADHD), obesity, hypoactive sexual desire disorder, and seasonal affective disorder (SAD). It has also been effective in bipolar depression and as an augmentation agent in patients with partial response to SSRIs. Overall, bupropion is a unique antidepressant with a broad therapeutic spectrum and a superior tolerability profile.

Bupropion first received U.S. Food and Drug Administration (FDA) approval in 1985. It was on the brink of release when a study by Horne et al. (1988) reported that 4 of 55 subjects with bulimia experienced seizures during treatment with the medication. Bupropion was withdrawn from the market pending additional investigation of its effects on seizure thresholds. Further research revealed that the risk of seizures increased from 0.3% to 0.4% at dosages of 450 mg/day to almost 2% at dosages of 600 mg/day. Bupropion was reintroduced in 1989 with a maximum recommended dosage of 450 mg/day (Davidson 1989). The original immediate-release (IR) formulation of bupropion was dosed three times daily. In an effort to improve tolerability and safety, a sustained-release (SR) formulation of bupropion, dosed twice daily, was subsequently introduced, and a once-daily extended-release (XL) formulation became available in 2003. Bupropion XL is now the most commonly prescribed formulation, as once-daily dosing is thought to optimize tolerability and adherence (McLaughlin et al. 2007).



Among its many uses stated above, this medication was also FDA approved for the indication of smoking cessation under the name Zyban in 1997, and bupropion XL was FDA approved for

prophylaxis of seasonal depression in 2006. Over time, investigators continue to discover more uses and indications for this multifaceted medication.

STRUCTURE–ACTIVITY RELATIONS

Bupropion, 2-(tert-butylamino)-1-(3'-chlorophenyl)propan-1-one, is a monocyclic antidepressant and member of the aminoketone group (Figure 20–1). It was designed as a simple chemical structure that would, in vivo, result in relatively innocuous metabolites (Mehta 1983). Bupropion works as an organic base with a high degree of both water and lipid solubility, resulting in good systemic absorption. Its benign side-effect profile in comparison with that of tricyclic and tetracyclic antidepressants is due to the absence of heterocyclic rings as well as other common functional groups (Mehta 1983). Bupropion has little potential for abuse (Griffith et al. 1983). Mehta (1983) discussed the many significant differences between the chemical structures of bupropion and psychostimulants and accounted for the varying pharmacological and clinical effects (Hudziak and Rettew 2004).

PHARMACOLOGICAL PROFILE

Although similar to classical antidepressants such as TCAs and SSRIs in therapeutic efficacy, bupropion is considered to be an atypical antidepressant with a mixed neuropharmacological profile. Bupropion inhibits the reuptake of dopamine (DA) and norepinephrine (NE) by acting as a nonselective inhibitor of the dopamine transporter (DAT) and the norepinephrine transporter (NET). Studies show that bupropion also acts as an antagonist to nicotinic acetylcholine (nACh) receptors. Alternatively, bupropion does not act as an inhibitor of monoamine oxidase A or B, nor are the effects of bupropion mediated by serotonin (Ascher et al. 1995).

Dwoskin et al. (2006) reported that bupropion inhibits DA reuptake into rat striatal synaptosomes, NE reuptake into rat hypothalamic synaptosomes, and, less potently, serotonergic reuptake into rat hypothalamic synaptosomes (Ascher et al. 1995; Dwoskin et al. 2006; Ferris and Beaman 1983; Ferris et al. 1982; Workman and Short 1993). In fact, Ferris et al. (1983) reported that bupropion is six times more potent than imipramine in blocking DA reuptake.

Recent studies demonstrate that bupropion also raises DA concentrations by causing a rapid and reversible increase in vesicular DA reuptake via cellular redistribution of the vesicular monoamine transporter (VMAT2) protein. By increasing the presynaptic pool of DA available for release, the concentration of DA in the extracellular space is further augmented, adding to the therapeutic efficacy of this compound (Dwoskin et al. 2006; Rau et al. 2005).

Although more is known about the dopaminergic effects of bupropion, interaction with the

noradrenergic system also plays an important role in the drug's antidepressant activity. Bupropion is a weak competitive inhibitor of NE; in comparison with imipramine, it is 65-fold less potent (Ferris and Beaman 1983).

Along with inhibiting DA reuptake and NE function, bupropion has also been found to act as an nACh receptor antagonist. Research with various cellular expression systems has elucidated the ability of bupropion to interact with specific nACh receptors. Bupropion has been shown to work by noncompetitive inhibition of nACh receptors (Dwoskin et al. 2006). This action may partially contribute to the efficacy of bupropion not only as an antidepressant but also as an agent for tobacco cessation.

It has been noted that bupropion shares some structural and neurochemical properties with sympathomimetics and has a phenylethylamine skeleton similar to that of amphetamine. Although it resembles amphetamine in certain structural aspects, bupropion does not increase the spontaneous release of catacholamines in rat striatum and hypothalamus. A study by Griffith et al. (1983) examining the effect of bupropion and amphetamine in previous amphetamine abusers concluded that bupropion had little abuse potential in humans.

Although a great deal remains to be learned about the complete pharmacological profile of bupropion, what we do know is significant. In summary, bupropion is known to be an atypical antidepressant with a mixed pharmacological profile. It exerts its effect by blocking DA and NE reuptake as well as by antagonizing nACh receptors. It does not work through inhibition of monoamine oxidase and does not block serotonin reuptake. As Dwoskin et al. (2006) emphasized, in the future it will be important to elucidate which specific mechanism, or combination of mechanisms, is responsible for the clinical efficacy of bupropion.

PHARMACOKINETICS AND DISPOSITION

Bupropion is rapidly absorbed in the gastrointestinal tract after oral administration (Findlay et al. 1981; Jefferson et al. 2005). Absorption has been found to be close to 100% (Schroeder 1983). After first-pass metabolism, systemic bioavailability of the drug is decreased (Jefferson et al. 2005; Schroeder 1983). Peak plasma levels occur within 2 hours for the IR preparation. As expected, absorption is prolonged for the SR and XL formulations, for which peak plasma concentrations occur at 3 and 5 hours, respectively (Jefferson et al. 2005). Although absorption times differ, the three forms are considered to be bioequivalent (Fava et al. 2005; Jefferson et al. 2005; Physicians' Desk Reference 2005). Food does not impair absorption, and protein binding ranges from 82% to 88%. Jefferson et al. (2005) noted that this level of protein binding is not high and is not likely to be of clinical importance. The elimination half-life for bupropion is 21(±9) hours, and the half-life for hydroxybupropion, the major metabolite of bupropion, is close to 20 (±5) hours (Clayton 2007; Jefferson et al. 2005). Steady state occurs in 7–10 days. Finally, excretion in the urine occurs with 0.5% of the drug unchanged (Findlay et al. 1981).

Bupropion is extensively metabolized by the liver. The major metabolite, hydroxybupropion, is formed by cytochrome P450 (CYP) 2B6 (Hesse et al. 2000; Kirchheiner et al. 2003). The peak plasma concentration of hydroxybupropion at steady state is four- to sevenfold higher than that of bupropion. Although CYP2B6 is the primary isoenzyme involved in bupropion's metabolism, other isoforms, including 1A2, 2A6, 2CP, 2D6, 2E1, and 3A4, play a small role (Hesse et al. 2000; Kirchheiner et al. 2003). Bupropion inhibits CYP2B6 and therefore may interfere with drugs that are metabolized by this enzyme, such as desipramine and nortriptyline (Hesse et al. 2000; Jefferson et al. 2005).

Besides hydroxybupropion, other active metabolites of bupropion are threohydrobupropion and erythrohydrobupropion. These two pharmacologically active metabolites have the capacity to accumulate at levels nearly five times greater than the parent compound and can have half-lives up to 43 hours (Golden et al. 1988; Jefferson et al. 2005; Posner et al. 1985; Preskorn et al. 1990).

In examining the pharmacokinetics of bupropion in regard to gender, age, and smoking status, no

significant effect has been found and definitive results have been inconclusive (Daviss et al. 2006; Hsyu et al. 1997; Jefferson et al. 2005; Stewart et al. 2001; Sweet et al. 1995). Nevertheless, it is important to monitor elderly patients more closely as they often have greater clinical issues with tolerability. One study with the elderly found evidence for an extended half-life of bupropion and for accumulation of metabolites (Sweet et al. 1995). For patients with impaired renal function, dosing should be initiated at lower levels. Worrall et al. (2004) showed that accumulation of two of the metabolites of bupropion—hydroxybupropion and threohydrobupropion—was significantly elevated in patients with end-stage renal disease compared with historical controls. Moreover, the metabolism of bupropion is also negatively affected in hepatic disease. Two studies have found increased levels of both bupropion and hydroxybupropion or of bupropion alone in patients with hepatic dysfunction (DeVane et al. 1990; Jefferson et al. 2005; Physicians' Desk Reference 2005). These results prompted the manufacturer to recommend that bupropion be used with caution in patients with mild to moderate liver disease and with extreme caution in patients with severe liver disease (Physicians' Desk Reference 2005).

MECHANISM OF ACTION

Despite considerable time and energy spent in elucidating bupropion's mechanism of action, what we know is limited. Preclinical data indicate that bupropion does not work by binding to postsynaptic histamine, α- or β-adrenergic, or serotonin receptors, nor does it inhibit monoamine oxidase (Ascher et al. 1995; Baldessarini 2001; Fava et al. 2005; Stahl et al. 2004). Thus, it is the only newer antidepressant without substantial serotonergic activity (Ascher et al. 1995; Richelson 1996; Stahl et al. 2004). Most researchers believe, and there is strong evidence to support, that the neurochemical mechanisms mediating the antidepressant effects of bupropion are from DA and NE reuptake inhibition. As discussed earlier, evidence shows that bupropion is a nonselective inhibitor of the DAT and the NET and is also an antagonist at neuronal nACh receptors (Dwoskin et al. 2006).

Bupropion's three major metabolites—hydroxybupropion, threohydrobupropion, and erythrohydrobupropion—play a crucial role in its antidepressant activity (Physicians' Desk Reference 2005). Together, bupropion and its active metabolites have been shown to decrease the reuptake of NE and DA into rat striatal and rat hypothalamic synaptosomes (Ascher et al. 1995; Ferris and Beaman 1983; Ferris et al. 1983; Miller et al. 2002). Moreover, in vitro studies have demonstrated that bupropion and its active metabolites inhibit both the NE and the DA human transporters (described in Fava et al. 2005).

Although other antidepressants often produce their effects by downregulation of the postsynaptic noradrenergic receptors, bupropion differs in how it interacts with noradrenergic systems in that it decreases the firing rate of neurons in the locus coeruleus in a dose-dependent manner (B. R. Cooper et al. 1994; T. B. Cooper et al. 1984). Acute administration of bupropion not only decreases firing of brain stem NE and DA neurons but also increases extracellular NE and DA concentrations in the nucleus accumbens (Fava et al. 2005). Furthermore, the efficacy of bupropion and hydroxybupropion has been shown to decrease in animal models when NE- or DA-blocking drugs are administered (B. R. Cooper et al. 1980).

INDICATIONS AND EFFICACY

Primary Indications

Depression

The efficacy of bupropion for the treatment of major depressive disorder is supported by many clinical trials. All three forms have proven to be equally useful in the treatment of depression. In 1983, Fabre et al. published results of a multicenter trial showing that bupropion IR at dosages of 300–600 mg/day was significantly better than placebo in reducing symptoms of depression. This was followed
